New treatment options for MAHC are being developed but have not yet been approved for clinical treatment. Cinacalcet is a calcimimetic that works by decreasing PTH production. It has been used to successfully to treat hypercalcemia secondary to parathyroid carcinoma and is approved for this indication by the US Food and Drug Administration.[157,158] Cinacalcet has also been reported in small case series to be successful for off-label use to treat MAHC.[159,160] Side effects of this treatment include nausea, vomiting, and headaches. Additional studies are needed to determine cinacalcet's therapeutic potential for MAHC. Lastly, anti-PTHrP and anti-PTH1R antibodies are being tested in animal models.[157,158,161,162] These novel therapies may offer additional treatment options in patients who are refractory or nonresponsive to current MAHC therapies.

Finally, it must be underscored that all the treatment options for MAHC described earlier can be used to stabilize the patient until the underlying malignancy can be appropriately treated, as successful antitumor therapy is the only true cure for MAHC.

KEY POINTS

- Hypercalcemia of malignancy can be effectively treated by lowering bone resorption and by treating the underlying malignancy if possible.

Summary, 970

PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism (PHPT) is demonstrated by a biochemical diagnosis resulting from excess synthesis and secretion of parathyroid hormone (PTH) owing to a loss of normal feedback regulation of the PTH receptor. Historically, it has been characterized by hypercalcemia in conjunction with elevated, or inappropriately normal, serum PTH levels in the setting of normal renal function. Recently, the normocalcemic PHPT phenotype has been recognized and categorized.[1] Causes of secondary hyperparathyroidism (SHPT) and tertiary hyperparathyroidism (THPT) must be excluded to unequivocally establish the diagnosis.

KEY POINTS: Primary Hyperparathyroidism

- Primary hyperparathyroidism requires biochemical diagnosis based on serum calcium and parathyroid hormone levels and absence of secondary hyperparathyroidism.
- Ideal management is a team approach (medical and surgical endocrinologists, imaging specialists).
- Surgery is the only curative treatment option.
- All symptomatic patients should be referred for surgical intervention.
- Asymptomatic patients need careful evaluation, as a subset will have indications for surgery.

Clinical Presentation

Before the development of automated laboratory equipment allowing for inexpensive and rapid measurement of serum calcium, the diagnosis of PHPT was rare. Generally, patients were evaluated after presenting with significant signs of advanced disease such as nephrolithiasis, peptic ulcers, or bone disease. With the development of multichannel serum chemical analyzers in the 1960s, measurement of serum calcium became routine, and by the 1970s PHPT was most often found because of incidental identification of hypercalcemia, particularly in the United States and Europe.[2,3] The overall prevalence in the United States is estimated at approximately 0.86%. It affects women significantly more than men, with an incidence ratio of 4:1 and peak incidence in the early postmenopausal period.[4]

Although the vast majority of patients in the United States do not present with the classic symptoms and signs, PHPT is associated with a multisystem clinical syndrome manifesting in the skeletal, renal, gastrointestinal, neurologic, and psychiatric systems. The previous hallmarks of the disease are now much less common, with osteitis fibrosis cystica occurring in less than 2% and nephrolithiasis in less than 20% of cases.[5] Once PHPT is diagnosed biochemically and causes of SHPT/THPT have been ruled out, providers must determine the appropriate next steps in management.

Indications for Surgery

Because surgery is the only curative treatment for PHPT, parathyroidectomy was previously identified as the standard of care for all patients presenting with PHPT. This is still the case for patients presenting with significant symptoms and overt signs of disease, such as fragility fractures, nephrolithiasis, peptic ulcer disease, or significant neurocognitive deficits. However, over the last four decades, with the change in severity of the disease at the time of diagnosis, questions have arisen regarding whether all patients need surgical intervention, especially in the growing cohort with asymptomatic PHPT. As such, in 1990, 2002, 2008, and 2013 international multidisciplinary expert workshops were assembled to discuss this issue, evaluate the relevant literature, and develop guidelines for the diagnosis, recognition, and management of this disease.

Following the fourth international workshop in Florence in 2013, updated guidelines were published. In these, Bilezikian et al.[6] indicate that all patients with confirmed PHPT and traditional signs and symptoms should undergo parathyroidectomy. In asymptomatic patients, defined as those with biochemically confirmed PHPT who lack overt signs and symptoms, guidelines for surgical recommendation are based on markers of more severe disease or disease more likely to progress. Observation is an acceptable option in those who do not meet these criteria, as long as they are able to comply.[6] Subsequently, in 2016, the American Association of Endocrine Surgeons convened a multidisciplinary panel and, using the American College of Physicians grading system, published consensus recommendations based on the literature.[7] Similarly, parathyroidectomy was recommended for all symptomatic patients. A summary of common symptoms and signs is detailed in Table 56.1.[7,8] Surgery is also recommended for those with evidence of severe disease, those at risk for progression, and those who are unreliable, unable, or unwilling to comply with surveillance. A summary of surgical recommendations for asymptomatic patients can be found in Table 56.2.[7]

Despite these consensus guidelines and straightforward recommendations, interpretation is more nuanced. Primarily, the issue lies in distinguishing between symptomatic and asymptomatic PHPT in those not presenting with obvious classic symptoms and signs. There are an array of nonspecific, subtle, common symptoms that are also associated with PHPT, including fatigue, exhaustion, weakness, polydipsia, polyuria, nocturia, constipation, bone pain, back pain, joint pain, depression, memory loss, loss of appetite, nausea, heartburn, and pruritus.[8] These symptoms, while difficult to quantify and unequivocally attribute to PHPT, affect the perception of quality of life. The true determination of causality and severity is only brought to light post parathyroidectomy.[9-15] Accordingly, those recommending surgical intervention must delve into the history to determine whether a patient is symptomatic. Additionally, although the guidelines suggest that asymptomatic patients that do not meet criteria for severe disease may be observed without surgery, they also state that surgery is always an acceptable option. Patients and providers should be given the opportunity to discuss the potential benefits of intervention, as well as the costs, success rates, and complication rates associated with surgery.

The natural history of PHPT has been well studied. Even in those with asymptomatic PHPT, although it occurs slowly, 25% to 33% of patients will have disease progression and eventually meet criteria for surgery, and some of the more serious consequences of unchecked disease, including bone loss, renal dysfunction, and cardiovascular risk, are preventable with early intervention. Additionally, prospective randomized controlled trials have shown that symptoms, specifically neurocognitive function and quality of life, improve following parathyroidectomy.[3,12-14,16,17] Accordingly, patients with a clear diagnosis of PHPT should be thoroughly evaluated and given the opportunity to discuss surgical and medical management with an experienced parathyroid surgeon, including the risks and benefits of intervention. Patients who have symptoms or who are asymptomatic and meet surgical criteria should receive

TABLE 56.1 Common Symptoms and Signs of Primary Hyperparathyroidism

System	Sign/Symptom
Renal	Symptomatic nephrolithiasis
	Recurrent nephrolithiasis
	Polyuria
	Nocturia
	Polydipsia
Skeletal	Osteitis fibrosa cystica (rare)
	Long bone pain
Gastrointestinal	Gastroesophageal reflux
	Acute pancreatitis with severe hypercalcemia
	Constipation
	Loss of appetite
	Nausea
Neuromuscular	Proximal muscle weakness (rare)
	Muscular atrophy (rare)
	Easy muscle fatigue
	Generalized weakness
Neuropsychiatric/cognitive	Mental status changes (rare)
	Obtundation (rare)
	Frank psychosis (rare)
	Progressive fatigue
	Exhaustion
	Depression
	Anxiety
	Emotional lability
	Sleep disturbances
	Worsening memory/memory loss
	Inability to concentrate

TABLE 56.2 Guidelines for Parathyroidectomy in Asymptomatic Patients

Measure	Surgical Indication[a]
Age	Less than 50 years
Serum Calcium	>1 mg/dL (>0.25 mmol/L) above upper limit of normal
Skeletal	a. T-score of ≤–2.5 (osteoporosis)
	b. Fragility fracture
	c. Vertebral fracture by imaging
Renal	a. Creatinine clearance <60 mL/min
	b. 24-hr urine calcium >400 mg/dL (>10mmol/dL) AND increased stone risk by biochemical stone risk analysis
	c. Imaging evidence of nephrolithiasis – x-ray, ultrasound, or computed tomography
	d. Nephrocalcinosis on imaging

[a] Surgery also indicated in patients unwilling or unable to comply with medical surveillance.

(Data from Wilhelm SM, Wang TS, Ruan DT, et al. The American Association of Endocrine Surgeons Guidelines for Definitive Management of Primary Hyperparathyroidism. *JAMA Surg.* 2016;151(10):959–968.)

a strong recommendation for surgery. Patients who are asymptomatic and do not meet guideline criteria should be informed that surgery is an option that may offer benefit when compared with observation.

Preoperative Preparation

Diagnosis. One should consider referral of all patients with hyperparathyroidism (HPT) to an endocrinologist before surgical intervention. From the surgical perspective, the first step in preoperative preparation of a patient with PHPT is confirmation of the diagnosis. Although most endocrinologists perform exquisite evaluations confirming the diagnosis, less experienced practitioners can miss subtle confounding issues, including mild forms of SHPT or familial forms of HPT. Because this is a biochemical diagnosis, the surgeon needs to review the levels of serum calcium and intact PTH and assess renal function. They must also evaluate the patient's serum creatinine, 25-hydroxy-vitamin D, and 24-hour urine collection of calcium. Baseline bone mineral density examination is also beneficial, as the values can affect recommendations for surgery. Based on review of these values, combined with a detailed history, surgeons will make a recommendation regarding intervention.

Parathyroid Imaging. Parathyroid imaging studies, which can be broadly classified into noninvasive and invasive, are designed to provide surgeons with a map to assist exploration. They are not diagnostic studies. They provide an anatomic landscape to locate enlarged parathyroid glands in eutopic and ectopic positions. Some of these common locations are illustrated in Fig. 56.1.[7] Historically, the surgical approach for parathyroidectomy was bilateral cervical exploration with examination of all glands. However, PHPT is caused by a single parathyroid adenoma in approximately 85% of patients, and resection of this gland alone results in a sustainable cure. The remaining patients have multigland disease, generally four-gland hyperplasia (10%–15%) or double adenomas (3%–5%) and require resection of more than one gland to achieve operative cure.[3,18] The purpose of localization studies is to identify a target adenoma in those with single-gland disease, allowing the surgeon to perform a focused exploration, or to suggest the presence of multigland disease.

Noninvasive preoperative localization studies include cervical ultrasound, sestamibi-technetium-99m scintigraphy, usually with single-photon emission computed tomography (SPECT), four-dimensional parathyroid computed tomography (4D CT), and magnetic resonance imaging (MRI). In a patient who has not had prior anterior cervical exploration, localization studies are used to determine whether the patient is a candidate for focused parathyroidectomy or if bilateral neck exploration should be planned from the outset (Fig. 56.2). The aforementioned imaging techniques have advantages and disadvantages, and the selection of a study is dependent on the overall clinical picture, local availability of quality equipment, and experience of those interpreting the studies. The most commonly used protocols are either ultrasound, often with a corresponding sestamibi-SPECT, or ultrasound with 4D CT. Invasive preoperative localization studies include image-guided fine-needle aspiration of an identified lesion for cytologic evaluation and PTH measurement and parathyroid angiography with selective venous sampling and are reserved for patients in whom surgical intervention is required in a reoperative field. Furthermore, in the reoperative case, noninvasive studies are often adequate, and invasive studies can be obviated. As such, invasive localization studies will be reviewed in a later section when discussing reoperative cases.

KEY POINTS: Principles of Parathyroid Imaging

- Parathyroid imaging is not a diagnostic procedure.
- All imaging studies are not created equally: quality varies dramatically in different centers.
- The purpose of imaging is surgical planning, and imaging should only be done if surgery is indicated/planned.
- Negative imaging is not a contraindication for surgery.
- Non-Invasive imaging generally consists of ultrasound, sestamibi +/- single-photon emission computed tomography, four-dimensional parathyroid computed tomography, or magnetic resonance imaging.
- Invasive imaging, including image-guided aspiration and parathyroid angiography with selective venous sampling, is reserved for reoperative cases.

Ultrasound. Ultrasound is noninvasive and inexpensive, avoids ionizing radiation exposure, and has the benefit of screening for concomitant thyroid disease that could be addressed simultaneously during surgery. It is highly dependent on the skills of both the technician and the interpreter, with a true-positive rate ranging between 50% and 75%, which improves when combined with sestamibi or 4D CT to around 90%.[19-21] It is more accurate with larger glands and in the setting of adenoma rather than hyperplasia. Typically, a positive ultrasound demonstrates an enlarged parathyroid as a hypoechoic homogeneous extrathyroidal mass, often with a polar feeding blood vessel (Fig. 56.3). Normal parathyroid glands are unlikely to be visualized on ultrasound because of their small size. However, enlarged glands can also be missed, especially in the setting of mild disease, multigland disease, obese patients, mediastinal glands, or posterior glands. Although all imaging techniques are affected by the quality of the equipment, this technique relies heavily on the experience and proficiency of the ultrasonographer.

Sestamibi–Single-Photon Emission Computed Tomography. Sestamibi-SPECT is the most commonly used study for localization of parathyroid disease. Sestamibi-technitium-99m scans are dependent on mitochondrial uptake in parathyroid tissue (Fig. 56.4). Uptake is also noted in salivary glands, lymph nodes, and thyroid nodules, which

can lead to false-positive studies. When performed in conjunction with a low-dose CT, the images can be fused for improved localization with fewer false-positive findings (Fig. 56.5). Reported sensitivities range widely, generally between 80% and 90%.[22] Sestamibi-SPECT allows for improved visualization of ectopic glands compared with ultrasound, specifically of the mediastinal and posterior glands. Similar to ultrasound, this technique has limited ability to identify multigland disease and small adenomas.[22-24]

Four-Dimensional Computed Tomography. 4D CT uses multiple runs and intravenous (IV) contrast to add the dimension of time to three-dimensional cross-sectional CT imaging. By scanning before and sequentially following contrast administration, structures in the neck and mediastinum are imaged and evaluated for the rapidity of uptake and washout of contrast, and thin cuts provide detailed images with anatomic and functional information (Fig. 56.6). Relying on their vascularity, hyperfunctioning parathyroid glands have low attenuation precontrast, with rapid uptake and washout of contrast in the arterial and delayed images, respectively, compared with surrounding structures and normal glands.[25] The sensitivity of 4D CT is better than that of sestamibi and ultrasound (88% vs. 65% and 57%, respectively) and

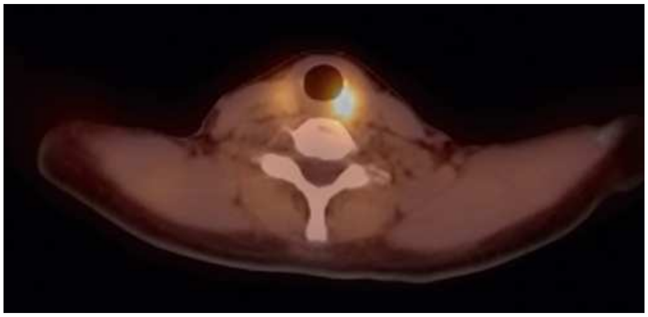

Fig. 56.5 Fused single-photon emission computed tomography/computed tomography demonstrates uptake consistent with a parathyroid adenoma.

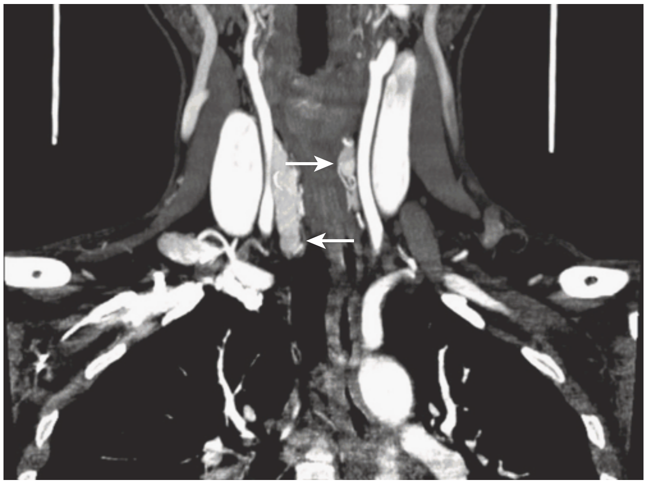

Fig. 56.6 Arterially-enhancing parathyroid adenomas on four-dimensional computed tomography (*arrows*).

predicts multigland disease better than sestamibi (85% vs. 25%–45%,).[25-27] Contrary to ultrasound and sestamibi, 4D CT exposes the patient to ionizing radiation and requires iodinated contrast administration. Accordingly, its use is minimized in certain populations, such as patients under the age of 30 years to reduce the exposure of the thyroid gland to ionizing radiation, those with renal insufficiency to avoid the contrast load to compromised kidneys, those with documented contrast allergy, or those with differentiated thyroid carcinoma with the anticipated need for postoperative radioactive iodine treatment in whom the iodinated contrast load would delay this treatment.[28]

Magnetic Resonance Imaging. MRI images demonstrate parathyroid adenomas as isointense structures relative to the surrounding muscle, with low intensity on T1-weighted images, intense contrast enhancement, and hyperintensity on T2-weighted images (Fig. 56.7). Although some prefer this method because of the lack of ionizing radiation, with the development of 4D CT it is not as commonly used, except in pregnant patients. Its sensitivity is reported to be 69% to 88%.[25]

Imaging is helpful for operative planning; however, negative imaging should not affect the decision for initial surgery because the biochemical diagnosis and surgical indications are not dependent upon imaging. Imaging is used for surgical preparation, strategy, and deciding between focused versus bilateral exploration. With or without positive imaging, the surgeon must be prepared for bilateral exploration and evaluation of all four glands in all cases. In the setting of negative preoperative imaging, the incidence of multigland disease occurs in as many as 37% to 50% of cases, although the glands are likely to be asymmetrically mildly enlarged.[29,30]

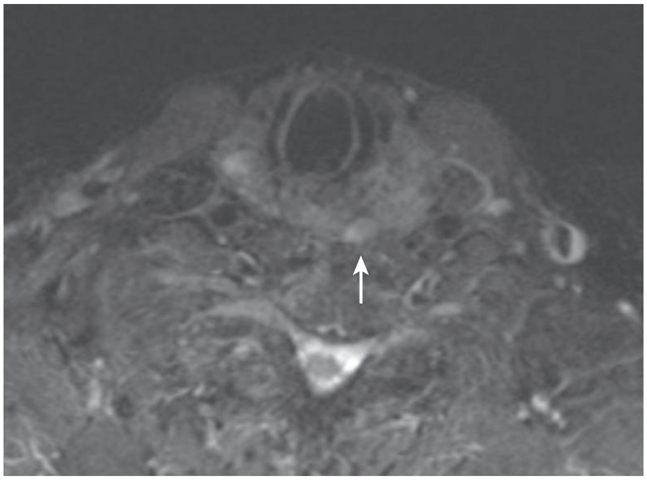

Fig. 56.7 Parathyroid adenomas appear bright on T2-weighted magnetic resonance imaging (*arrow*).

KEY POINTS: Imaging Shortcomings

- Imaging quality is highly variable because of different protocols, devices, and technicians.
- Ultrasound is particularly user dependent.
- All imaging studies are less sensitive in multigland disease.
- Reported imaging sensitivities and specificities rarely include operative and pathologic findings with biochemical confirmation of cure, thus likely are inaccurate estimates.

Parathyroid Development. The embryological development and migration of the parathyroid glands play a role in surgical planning. The inferior parathyroid glands are derived from the endoderm of the third pharyngeal pouch, developing with the thymus. During gestation, these glands descend inferomedially, following the path of the thymus, until they reach their final location, typically posterior to the inferior aspect of the thyroid gland, anterior to the recurrent laryngeal nerve (RLN). The superior parathyroid glands are derived in the fourth pharyngeal pouch with the c-cells of the thyroid and descend during gestation, attaching to the posterior surface of the thyroid gland, posterior to the RLN. Because of the gestational migration of these glands, their final positions can be quite varied, and may be found anywhere along the track from the angle of the mandible to the mediastinum, as shown in Fig. 56.1. As they travel a farther distance, the inferior parathyroid glands are more variable in location than the superior glands.

Knowledge of this embryologic migration and resultant anatomical variation is quite important in surgical planning and during exploration. Superior and inferior parathyroid glands identified during surgery are classified as such based on their relationship to the RLN. A parathyroid gland identified posterior and lateral to the nerve is a superior gland, and a gland identified anterior and medial to the nerve is an inferior parathyroid gland, regardless of which is more caudad or cephalad. Ectopic superior glands can be found in the paraesophageal or retroesophageal space, within the thyroid gland, in the carotid sheath, or in the posterior mediastinum. Ectopic inferior parathyroid glands can be found within the thymus, perithymic fat, thyrothymic ligament, thyroid gland, anterior mediastinum, or carotid sheath.

Preoperative Vocal Cord Evaluation. In the assessment of the patient, one additional factor for the surgeon to consider, is vocal cord mobility. RLN palsy, either temporary or permanent, is a rare but potential complication of parathyroidectomy, and can result in significant morbidity. There is no clear consensus regarding routine preoperative assessment to evaluate vocal cord mobility and identify potential asymptomatic palsies or other issues that impair motion in the previously unexplored patient with a normal voice.[31] In contrast, all reoperative patients, as well as those with complaints of hoarseness or voice changes, should undergo preoperative assessment of vocal cord function.[31,32] This practice does not change or affect the rate of injury; however, it does provide critical information to the surgeon.

Indirect mirror laryngoscopy or direct laryngoscopy, generally with a flexible fiberoptic nasopharyngoscope, allows for visualization of the vocal cords and evaluation of their movement with phonation, breathing, and coughing.[33] With this, the surgeon is able to assess for bilateral movement and symmetry of motion. Alternatively, transcutaneous ultrasound can be used to view the larynx and the vocal cords. This technique also allows for real-time cord evaluation, as well as assessment for other abnormalities; however, it is less reliable, especially in older patients, and other subtle abnormalities can be missed.[33] CT and MRI images can be examined for vocal cord symmetry and size and be used as an indication of function, but, without real-time input, are less reliable and more difficult to interpret. Although occasionally useful, it is unlikely that imaging-based evaluation of the vocal cords will ever replace the gold standard of direct or indirect laryngoscopy.

Operative Approaches

Intraoperative Parathyroid Hormone Assay. Understanding and interpreting PTH metabolism and levels are critical in the evaluation of this disease. Although it is not always used or available, one cannot discuss parathyroid surgery without reviewing intraoperative PTH measurement, as this is a major factor in determination of surgical approach. When considering use of an intraoperative PTH assay, the surgeon needs to be adept at interpretation of the results. Additionally, there are other factors that need to be considered for ideal utilization. One needs a rapid assay platform for evaluation of intact PTH. Ideally, a turnover time of less than 15 minutes from blood draw to result allows for optimal surgical decision-making. The assay should be located in proximity to the operating room, preferably close enough for swift transfer of the blood specimen from the patient to the machine for analysis. Proper interpretation requires serial values, so the assay should have the ability to run multiple samples simultaneously. The surgeon must also know the causes of falsely elevated and low values, as well as how to interpret and troubleshoot should errors occur. The instruments are delicate and require maintenance and standard curve calibration, and a properly trained technician is required to centrifuge the specimen and run the assay. Thus, in areas with resource scarcity, this may not be easily available or implementable.

Intraoperative PTH measurement requires user interpretation, which can be complex and requires experience. A baseline PTH level is obtained immediately before surgery, run on the same assay. Generally, two criteria are used to indicate biochemical surgical cure: (1) the PTH level should fall from preoperative baseline by more than 50%, 10 to 15 minutes following resection of the target gland, and (2) the post-resection fall should result in a PTH level in the normal range. Additionally, the rate of change

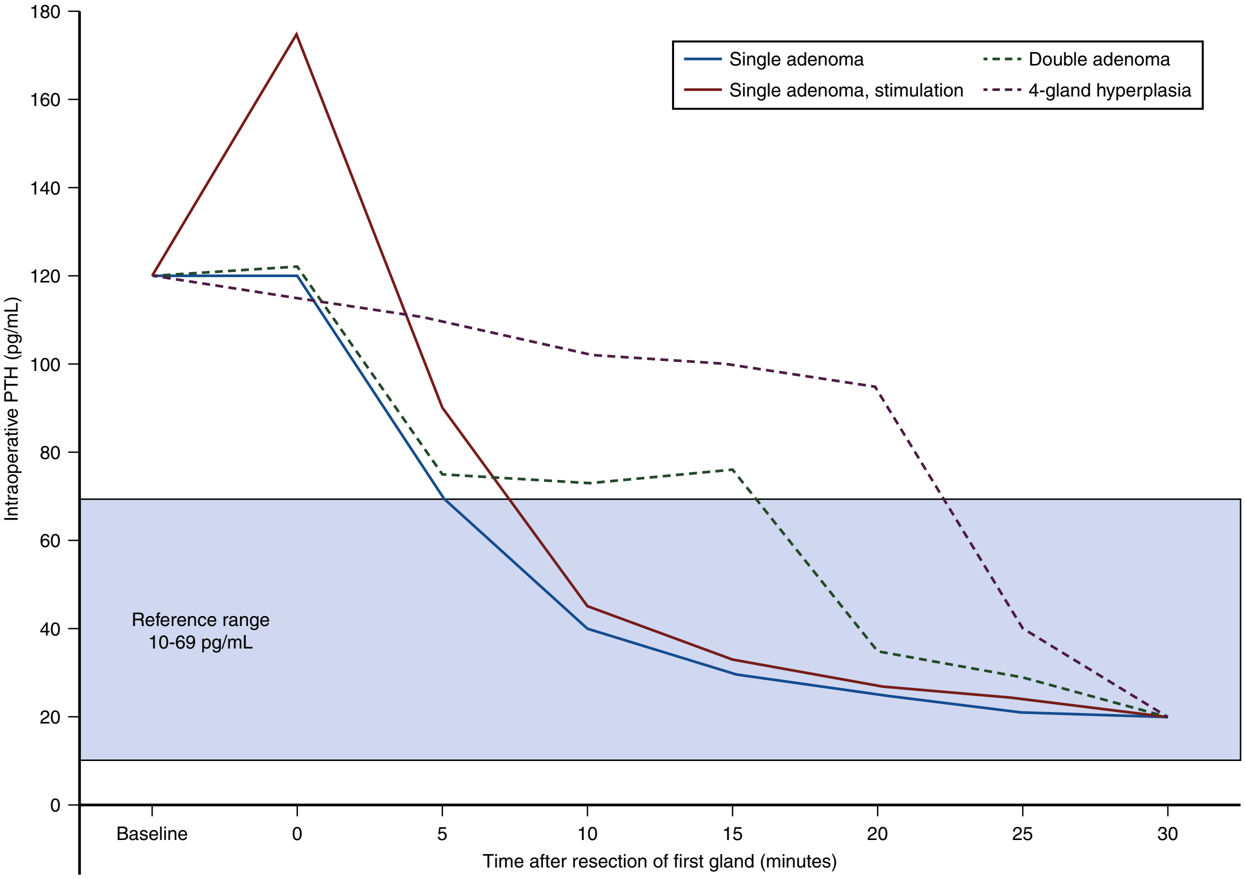

Fig. 56.8 Graphical representation of intraoperative parathyroid hormone (*PTH*) measurements.

and slope of the curve identified when plotting sequential intraoperative PTH levels gives significantly more information than a single value. In single-gland disease, resection of the culprit lesion generally results in a quick initial decline that slows or plateaus near the low end of normal. If the levels remain elevated or plateau at the upper end of normal, this generally indicates residual disease, and additional exploration and resection are necessary (Fig. 56.8). A computerized mathematical model was developed to use intraoperative PTH measures in individual cases to predict the chance of cure. This model could be used as a tool to aid the interpretation of these measurements, specifically in difficult cases.[34]

KEY POINTS: Intraoperative Parathyroid Hormone Assay

- Intraoperative parathyroid hormone (PTH) assay allows for focal exploration, dramatically altering surgical management.
- Surgeons must be adept at interpreting results, including false positives and false negatives .
- A rapid platform is optimal for intraoperative decision-making, ideally with results in <15 minutes.
- Assay should preferably be in proximity to the operating room to facilitate quick transfer of specimens.
- Interpretation is best with serial values, and the assay should be able to run simultaneous samples.
- Intraoperative PTH measurement showing a drop from immediate preoperative baseline by >50%, 10–15 minutes following target gland resection and into the normal range indicates intraoperative cure.

Operating Room Preparation. Before surgery, regardless of the planned approach, positioning is critical. The patient is placed in a comfortable semi-Fowler position with a thyroid pillow under the shoulder blades to allow for neck extension.[35] The use of an inflatable pillow allows for precise control over the pillow size to avoid stress on or overextension of the neck. Patients with cervical spine disease may require neutral positioning. A head ring is placed under the patient's occiput to stabilize the position during surgery. The arms are tucked to provide room for the surgical team to work.[36] Generally, a single large-bore peripheral IV can be used to administer fluids and medications intraoperatively, as well as to draw blood samples for intraoperative measurements of PTH. It is imperative to draw back blood diluted by IV fluids or medications before obtaining blood samples during intraoperative PTH measurements because this can otherwise artificially lower measured circulating PTH levels.[34]

Bilateral Cervical Exploration. A bilateral cervical exploration under general anesthesia is the traditional approach, with a rate of cure of greater than 95% and a low risk of complications when performed by experienced surgeons.[7] It is generally the planned approach in the setting of negative imaging or when family history or imaging studies suggest multigland disease. With this technique, the operator identifies and examines all parathyroid glands, then resects enlarged glands. Even when planned, bilateral exploration is not always necessary if single-gland disease can be confirmed. If, on exploration of the first side, the surgeon identifies one normal and one enlarged parathyroid gland, the enlarged gland can be resected and a rapid intraoperative PTH assay used to measure post-resection levels. If the PTH levels drop appropriately, indicating biochemical cure, no further exploration is required. Alternatively, if the post-resection levels do not show a sufficient decrease in circulating PTH, exploration should continue with further excision as indicated. In the case of four-gland hyperplasia, a subtotal parathyroidectomy is performed, where a sufficient volume (~30–50 mg) of one viable parathyroid gland is left at a single site *in situ*.[37] Although theoretically unnecessary in the setting of formal bilateral exploration and resection for four-gland hyperplasia, intraoperative PTH measurement is still useful to confirm sufficient debulking and adequate remnant function. A PTH drop into the range of 20 to 30 pg/mL is ideal in this circumstance.[37]

Minimally Invasive Parathyroidectomy. Given the prevalence of single-gland disease in PHPT, many prefer a focused approach with minimally invasive parathyroidectomy (MIP). In this technique, a unilateral cervical exploration is planned based on preoperative identification of a target lesion, presumed to be the incident parathyroid adenoma. This allows the surgeon to perform a limited exploration, identify the target gland, and resect the target gland only. With this approach, intraoperative PTH measurements are used to confirm single-gland disease and adequate resection and to demonstrate intraoperative biochemical cure. If these results do not reflect cure, additional exploration is required.[36,38] Some advocate for avoiding the use of intraoperative PTH monitoring in cases with good preoperative localization; however, studies show that, while cure is achieved at high rates in these cases, they may require additional surgery for multigland disease that was not identified with the initial exploration.[39-41]

The majority of MIPs throughout the world are performed under general anesthesia; however, in the proper setting, they can be performed on awake patients with regional anesthesia. Well-localized initial parathyroidectomies and selective reoperative parathyroidectomies can be performed by experienced teams without general anesthesia. Success with this approach requires an experienced anesthesia team to titrate sedation and a surgeon or anesthesiologist capable of administering a superficial cervical nerve block. Additionally, the surgeon will also often perform a field block. The positioning and preparation of the patient are the same as described above, with the addition of protective eyewear, and an ether screen is used to elevate the drapes off of the patient's face. Oxygen is administered, preferably by nasal cannula, and suction tubing is positioned to scavenge excess oxygen from the operative field and minimize fire hazard.[36,38] This set-up is depicted in Fig. 56.9.[35]

Endoscopic Approaches to Parathyroidectomy. As with many other surgical procedures, as technology has advanced, so has the drive to create further minimally invasive approaches. In 1996 an endoscopic approach to parathyroidectomy was described using video assistance and a laparoscope through a 1.5-cm incision in the neck.[42] This endoscopic technique for parathyroid and thyroid surgery evolved to permit remote access and avoid a neck incision altogether to improve cosmetic results, occasionally utilizing robotic assistance, including transaxillary, transbreast, combined axillary and breast, or retroauricular approaches. These techniques, while avoiding the visible cervical incision, imposed incremental risks compared with conventional surgery, and, because of the large flaps and extensive dissection required, are actually more invasive than conventional parathyroidectomy.[43] More recently, a transoral technique was developed that maintains the cosmetic benefits of remote access but is less invasive. This approach uses incisions in the oral vestibule of the lower lip and traverses the premandibular space to access the subplatysmal space opened in conventional parathyroidectomy.[43] These robotic and endoscopic approaches are more expensive, time-consuming, and difficult to learn and perform, as well as requiring sophisticated technology, solely for cosmetic benefit. Although they may play a role in select cases at select institutions, these are unlikely to become standard practice, especially as the majority of parathyroidectomies can be performed through an abbreviated Kocher incision measuring 2.5 to 3.5 cm in length. If the surgeon is able to place the incision parallel with a natural skin crease, the incision is often nearly invisible once fully healed.[44,45]

Intraoperative Adjuncts

Localization. There are several techniques that can be used to aid with identification or confirm intraoperative cure following resection of the target gland. The first is the use of intraoperative PTH measurements, as discussed. Additionally, this can also be used to confirm the tissue resected is actually a parathyroid gland, with *ex vivo* aspiration of the specimen sent for PTH measurement. Parathyroid tissue will have significantly elevated measurements of PTH, dramatically higher than serum levels and often higher than the scale of the assay. Lymph nodes, exophytic thyroid tissue, or other cervical soft tissues can appear similar to parathyroid tissue, and aspiration can confirm the presence or absence of parathyroid tissue in the specimen. Frozen section analysis can also be used to identify parathyroid tissue and can yield additional useful information such as gland weight and cellularity.

Some centers use preoperative sestamibi injection to aid with identification and resection. In these instances, a gamma probe is used intraoperatively to localize and identify the target lesion, then counts are used to measure the resected gland when compared with the background tissue to suggest single-gland disease and intraoperative cure. The excised lesion should contain more than 20% of the postexcision background radioactivity.[46-48] A large–field of view portable gamma camera has also been used in a similar way to show absent activity in the neck immediately following resection to indicate adenoma resection.[49]

Visualization of autofluorescence and indocyanine green is being used with increasing frequency in certain centers. This technique aids with localization and can also be used to assess gland perfusion following subtotal resection. In PHPT, indocyanine green angiography shows moderate to strong increased vascularization.[50] The use of IV methylene blue has been described for colorimetric localization to identify the parathyroid glands.[51]

Some prefer the use of high-resolution ultrasound guidance to aid in identifying target lesions. This is the least invasive imaging modality, does not use ionizing radiation, and can be reproduced intraoperatively, preincision. It is somewhat limited, however, following incision, as air in the tissues disrupts the appearance. Ultrasound has also been coupled with local methylene blue injection to aid with intraoperative identification.[51]

Some optical technologies described to evaluate the viability of parathyroid glands in the setting of thyroid surgery can also be used for localization of hyperfunctioning glands, including imaging with autofluorescence, 50-aminolevulinic acid, optical coherence tomography, laser speckle contrast imaging, dynamic optical contrast imaging, and Raman spectroscopy.[52]

Neuromonitoring. One of the major, although rare, risks of parathyroidectomy is RLN palsy. Intraoperative neurophysiological monitoring is being used increasingly. Neuromonitoring can only be done in procedures performed under general anesthesia with endotracheal intubation using a specialized endotracheal tube, and without the use of long-acting muscle relaxation. This adjunct to visual identification can assist in nerve localization and theoretically could reduce the incidence of trauma to the RLN. It does rely on correct implementation and interpretation of output, and training in analysis is required to prevent false security and increased harm.[53,54]

Postoperative Management

The immediate management and disposition of the postoperative patient are dependent on the extent of surgery performed. If a focused unilateral exploration was sufficient, there is no risk for permanent hypoparathyroidism, and if patients meet criteria, they may be discharged the day of surgery. Prophylactic supplementation with oral calcium is often initiated at this time. Furthermore, it is critical to instruct the patient on the symptoms of hypocalcemia and ensure access to reliable 24-hour communication with the surgical team to foster ease of remote management of potential postoperative hypocalcemia and minimize potentially dangerous hypocalcemic events. Having an experienced surgical team that can routinely follow up with the patient in the immediate postoperative period is imperative.

KEY POINTS: Postoperative Management

- Most patients have a straightforward postoperative course and are discharged home the same day.
- Postoperative events including severe hypocalcemia, bleeding, and airway obstruction can occur.
- A team approach is integral in inpatient and outpatient postoperative care.
- Hypocalcemia is treated with oral calcium and, if severe, intravenous calcium.
- Calcitriol can aid with stabilizing serum calcium levels in the immediate postoperative period.
- Serum calcium/intact PTH levels 6 months postoperatively indicate surgical cure if normocalcemic.

If surgery required bilateral exploration, or if the patient has had previous parathyroidectomy or contralateral cervical exploration, the risk for significant postoperative hypoparathyroidism is higher. In these instances, the patient should be considered for overnight hospital observation and measurement of postoperative serum calcium levels. With the lengthier half-life of calcium compared with PTH, it takes longer for hypocalcemia to manifest following an intraoperative drop in PTH levels. Hypocalcemia while in the hospital should be treated with oral calcium supplementation or, if severe, IV calcium. Calcitriol can also be used, with the goal of attaining a stable serum calcium level before discharge. Those with preoperative vitamin D deficiency, significantly elevated PTH with evidence of bone disease, normal to minimally elevated preoperative serum calcium levels, and an intraoperative drop in PTH levels of greater than 80% in 10 minutes are at increased risk for postoperative hypocalcemia.[55]

The patient is seen postoperatively, generally 1 to 2 weeks following surgery, for evaluation of the incision and measurement of serum calcium and intact PTH. The vast majority of patients demonstrate operative cure. However, those with evidence of persistent PHPT should be followed for consideration of reoperation and for specialized localization studies if surgery is planned. Those with initial results indicating cure should have medical endocrinology follow-up 6 months after surgery, with measurement of serum calcium and intact PTH. Although intraoperative PTH levels are used to demonstrate intraoperative or immediate postoperative cure, surgical cure is defined as the attainment of normocalcemia 6 months following parathyroidectomy. Those with an elevated serum calcium at this time may have persistent PHPT. Alternatively, if these values demonstrate normocalcemia, and patients develop hypercalcemia more than 6 months after surgery, it is considered recurrent disease. Patients with persistent or recurrent disease should be evaluated for reoperative parathyroidectomy, again with a detailed history and physical examination to determine the severity of disease, assessment of indications for surgery, and potential risks, which will be detailed later in this chapter.

A subset of patients following parathyroidectomy will demonstrate an elevated serum PTH level with a normal or low serum calcium level. This is usually attributed to SHPT in the setting of successful treatment of PHPT. Oral calcium supplementation resulting in suppression of PTH levels proves the diagnosis and serves as treatment. Some patients have elevated PTH levels postoperatively that eventually normalize without evidence of SHPT; however, the cause of this is yet unknown. Those in whom oral calcium supplementation does not suppress PTH levels into the normal range likely have early or mild multigland disease not identified at the initial operation.

Outcomes of Parathyroid Surgery

Operative Complications. In general, when performed by experienced high-volume surgeons, parathyroidectomy is a safe and effective surgery, with cure rates exceeding 95%. Major risks of surgery include RLN injury, hypocalcemia, and neck hematoma. Much less common complications included pneumothorax, stroke, and need for tracheostomy from bilateral RLN injury. RLN injury occurs in 0.5% to 1% of cases and usually results in hoarseness. This rate may be underestimated, as postoperative laryngoscopy is not routinely performed in the absence of symptoms. It can be temporary or permanent, depending on the degree of injury, and additional interventions such as vocal cord injection or medialization thyroplasty may be necessary.[44,45]

Some degree of hypocalcemia is common following parathyroidectomy owing to hypoparathyroidism but is usually mild, and temporary, especially if only one side of the neck is explored. It is managed with oral calcium and, occasionally, calcitriol. Permanent hypoparathyroidism with insufficient residual parathyroid function is rare. When it occurs, it results in long-term hypocalcemia in 0.1% of cases. It is managed with oral calcium and calcitriol supplementation.[44,45]

KEY POINTS: Operative Approach to Primary Hyperparathyroidism

- Sporadic primary hyperparathyroidism: ~85% single-gland disease, 10%–15% multigland hyperplasia, 3%–5% double adenomas.
- When localized disease is present, may attempt focal exploration with intraoperative parathyroid hormone (PTH) measurements.
- Four-gland exploration may be necessary for poorly localized cases, if PTH does not drop following focal exploration/resection, or if no access to intraoperative PTH assay/intraoperative adjuncts.
- In four-gland hyperplasia, treatment is subtotal parathyroidectomy, leaving a single-site remnant of ~30–50 mg of viable parathyroid gland .
- Intraoperative adjuncts including gamma probes are used by some to aid with gland identification.
- Endoscopic approaches to parathyroidectomy are done in select centers for cosmetic benefit.
- High-volume centers have operative success rates >95% and complication rates of 1%–2%; however, low-volume centers have poorer outcomes.

Postoperative bleeding resulting in a neck hematoma is a rare but potentially emergent situation. It is estimated to occur in 0.2% of cases and may require immediate return to the operating room for evacuation and hemostasis.[44,45] The airway can be very challenging in these cases, even in the absence of stridor or overt tracheal compression, because the hematoma can cause venous hypertension leading to laryngeal edema, making the airway difficult or impossible to visualize for standard intubation. Occasionally, in the setting of acute airway distress, it is necessary to open the incision at the bedside to protect the airway. In these cases, it is sometimes preferred or necessary to decompress the hematoma before attempting endotracheal intubation. Once the hematoma has been evacuated, the airway crisis is averted, and intubation of the trachea is usually unencumbered. Rarely, it is necessary to perform an awake, upright, fiberoptic intubation by the most experienced person available, given these potential issues.

Operative Cure. Success rates following parathyroidectomy with biochemical cure are usually excellent but are dependent on the experience of the surgeon and the center. Studies at high-volume centers report cure rates of around 99% for minimally invasive patients and 97% for bilateral explorations.[45,56] When discussing these success rates and contemplating surgery, it is important to consider that these studies are based on results of experienced surgeons in centers where the disease is well-understood, and high-quality imaging and intraoperative adjuncts are available. However, most parathyroid surgery is not performed by high-volume endocrine surgeons, and it is likely that outcomes from surgeons who do not perform this type of surgery often are not as favorable.[57]

The Health Care Utilization Project's National Inpatient Sample, maintained by the Agency for Healthcare Research and Quality, represents a stratified 20% sample of inpatient discharges from hospitals across the United States. Using this database, Adam et al. reported that, from 1988 to 2000, only 5% of parathyroid procedures were performed by a surgeon with 75% or greater endocrine case volume, and 78% of these cases were performed by surgeons with endocrine cases composing 25% or less of their practice.[58] Direct comparisons between surgeon volume and outcome following parathyroidectomy vary with regard to surgeon volume stratification, but demonstrate improved outcomes with increased surgeon volume.[57] Additionally, a higher percentage of operative failures occur at low-volume centers, and, based on the reoperative results, a proportion are considered potentially preventable.[57] For example, low-volume centers performed the initial surgery in 78% of cases considered to be avoidable following reoperative parathyroidectomy at a high-volume center.[59]

In a Scandinavian study, Malmaeus et al., using data from 1971 through 1980, directly compared high- and low-volume centers and reported that the cure rate in endocrine surgery centers was 90% versus 76% in general surgery clinics and 70% in centers that performed fewer than 10 parathyroid operations each year.[60] A subsequent Scandinavian quality register report did not categorize data based on surgeon or center volume; however, the overall cure rate was 91.9%, and postoperative hypocalcemia occurred in 11.4% of patients.[61] These results are not nearly as excellent as those reported by high-volume American centers and reflect that a substantial proportion of parathyroid surgeries in Scandinavia are not performed at high-volume centers.

SPECIAL CIRCUMSTANCES IN THE SURGICAL MANAGEMENT OF PRIMARY HYPERPARATHYROIDISM

Reoperative Parathyroid Surgery

Reoperative, remedial, or redo parathyroid surgery is performed in the setting of persistent disease or recurrent disease, or in patients who have undergone prior cervical surgery, such as thyroidectomy or anterior cervical fusion. These cases pose additional challenges and risks and are more complex. As such, it is beneficial to have these performed at a high-volume center by an experienced parathyroid surgeon.[57] These cases must be carefully reviewed to confirm the diagnosis and ensure an appropriate surgical indication. The recommendation for surgery in these cases is more complex, owing to increased operative risk, particularly in those with asymptomatic PHPT. Although these patients are likely to benefit from initial parathyroidectomy, remedial surgery has a higher rate of complications and a lower cure rate, altering the risk/benefit ratio. In general, reoperative parathyroidectomy is reserved for those with more symptomatic disease. Additionally, careful deliberation of the clinical history is warranted, with the consideration of the possibility of syndromic disease and a predisposition to recurrence.

KEY POINTS: Reoperative Parathyroid Surgery

- Patients with primary hyperparathyroidism and history of prior parathyroidectomy, thyroidectomy, or anterior cervical surgery are considered for remedial, reoperative, or redo parathyroid surgery.
- These cases have increased complexity, increased potential morbidity, and decreased rates of success.
- Reoperative cases are best managed at specialized centers.
- Imaging studies begin with noninvasive modalities, but invasive studies may be necessary.
- In high-volume centers, outcomes are still good despite increased difficulty.

The surgeon must carefully review all operative, pathologic, and interim data to have a clear picture of the previous operation(s) performed and subsequent course. Preoperative imaging searching for missed glands is also more challenging because the location of missed parathyroid glands is highly variable, as illustrated in Fig. 56.10.[62] Again, thorough knowledge of embryologic development and migration of the parathyroid glands is of utmost importance in these cases. Initial localization techniques are identical to unexplored cases, using ultrasound, sestamibi-SPECT, 4D CT, or MRI, ideally with two concordant studies before surgery. If these studies are not convincing, discordant, or nonlocalizing, invasive imaging may be necessary. If a lesion is seen on ultrasound, a fine-needle aspiration analyzed by cytologic evaluation and measurement of PTH in the aspirate can be performed to confirm that the identified lesion is a parathyroid gland. If the ultrasound cannot identify a target lesion, or if the lesion is not amenable to aspiration, parathyroid angiography with selective venous sampling can be performed, preferably with on-site rapid PTH measurement.[63] The PTH gradient between sites of venous sampling will regionalize the site of hormone drainage, suggesting the location of residual disease. These localization studies then provide the surgeon with a target for exploration. Reoperative exploration without identification of a target lesion is avoided whenever possible and should only be performed in severely symptomatic patients with failed localization studies, because of the added risk posed to these patients. This process is depicted in Fig. 56.11.

The success rates of reoperative parathyroid surgery are excellent when performed by high-volume surgeons, with cure rates reported to be 94% to 98%.[64-66] The rate of RLN injury in this patient population is higher, estimated at 2.3% based on a consecutive series of 130 reoperative parathyroidectomies.[62] Looking specifically at reoperations for persistent or sporadic adenoma, the rate of permanent RLN injury was 1.8%.[67] In reoperative cases, permanent hypoparathyroidism is of high concern because of the possibility that the target lesion may be the patient's only remaining functional parathyroid tissue. This risk is dependent on the extent of prior surgical exploration, as, even

without identification or resection, it is possible to inadvertently injure or devascularize the end-arterial blood supply to the other parathyroid glands. Dependent on the initial and reoperative course, it may be necessary to perform immediate parathyroid autotransplantation or parathyroid cryopreservation.

Hypercalcemic Crisis

A severe manifestation of PHPT, occurring in 1% to 6% of patients, is hypercalcemic crisis. This life-threatening, progressive event is characterized by severe hypercalcemia associated with dehydration, vomiting, renal failure, mental status deterioration, coma, and death. This is a medical emergency requiring immediate management with hydration and reduction of hypercalcemia.[68-70] Hospitalization is required for close monitoring and hydration with large volumes of IV fluid, occasionally with the addition of furosemide. If the hypercalcemia cannot be adequately improved with initial therapy, it may be necessary to add bisphosphonates, cinacalcet, or calcitonin to the regimen. Surgery is performed once the calcium levels have been appropriately decreased and renal function improves. It is ideal if surgery can be performed early in this course, circumventing the need for long-acting pharmacologic treatments, such as bisphosphonates, as these can complicate postoperative management because of severe hypocalcemia.

Inherited Syndromes

Although accounting for a minority of cases of PHPT, inherited forms occur in several syndromes. This is more likely in young patients who present with apparent sporadic disease, as up to 10% will have an inherited condition. The identification of those with inherited syndromes is quite important, because surgical management of inherited disease differs significantly from that of sporadic cases.[71]

Multiple endocrine neoplasia type 1 (MEN1), an autosomal dominant inherited syndrome resulting from mutations within the *MEN1* gene, is associated with PHPT, anterior pituitary tumors, pancreatic neuroendocrine tumors, foregut carcinoids (thymic, bronchial, or gastric), adrenal adenomas, a variety of skin lesions, and other benign tumors. PHPT is the hallmark of this syndrome, with relentless multigland disease and high penetrance, as over 98% of MEN1 patients have or will develop PHPT.[72] Parathyroidectomy is the principal management in these patients, but it must be done aggressively, being mindful of the age of the patient and likelihood of recurrence, and with the goal of minimizing morbidity, including permanent hypoparathyroidism.

KEY POINTS: Inherited Syndromes

- Although the majority of primary hyperparathyroidism (PHPT) cases are sporadic, there are a number of inherited forms.
- Up to 10% of young patients presenting with apparent sporadic disease have an inherited condition.
- Inherited syndromes should be suspected in patients with known family history of PHPT.
- Those with inherited disease are at increased risk for initial failure and recurrent disease.
- Surgery varies based on inherited disease and is best managed at specialized centers.

The 2020 National Comprehensive Cancer Network guidelines describe two surgical options when treating PHPT associated with MEN1: (1) subtotal parathyroidectomy leaving approximately 30 to 50 mg of parathyroid tissue *in situ*, with possible cryopreservation and possible transcervical thymectomy, or (2) total parathyroidectomy with immediate autotransplantation of parathyroid tissue, generally into the nondominant forearm, possibly with cryopreservation, and possible transcervical thymectomy.[73] There is still controversy as to which of these approaches is best in this population. In MEN1, all parathyroid tissue is abnormal; thus, there is a high risk of recurrent disease. Some studies quote recurrence rates of 30% to 40% with either approach, whereas others found higher rates following subtotal resections. If subtotal parathyroidectomy is performed, leaving a small remnant *in situ*, cervical reoperation would be necessary in the case of recurrence. However, following total parathyroidectomy with autotransplantation as many as one-third of patients have failure of the autograft, resulting in permanent hypoparathyroidism, which carries significant morbidity and rarely occurs following subtotal resection.[74]

Experienced surgeons generally also advocate for transcervical thymectomy at the initial operation to reduce the risk of thymic carcinoid tumor development, and because the thyrothymic ligament and thymus are common sites for parathyroid rests or supernumerary parathyroid glands. Also, transcervical thymectomy is much easier at the initial operation than at subsequent explorations. Thus, a commonly adapted approach to minimize cervical reoperation and permanent hypoparathyroidism is to perform a careful but aggressive subtotal parathyroidectomy with transcervical thymectomy at the initial operation, and, in the case of recurrence, perform a completion total parathyroidectomy with parathyroid autotransplantation to the forearm. If the patient develops subsequent episodes of recurrence, the transplanted tissue can be debulked.[75]

Multiple endocrine neoplasia type 2A (MEN2A) is an autosomal dominant inherited syndrome resulting from mutations in the *RET* protooncogene, predisposing patients to medullary thyroid carcinoma (MTC), PHPT, and pheochromocytoma. In MEN2A, the hallmark disorder is MTC, affecting nearly every patient, with PHPT occurring in 20% to 30%. PHPT in these patients is overall similar to that seen in sporadic patients, in that most cases result from apparent single-gland enlargement at any one time; however, the management is more complicated, because most have already undergone a prophylactic or therapeutic thyroidectomy for MTC. In these patients, if PHPT has not developed at the time of thyroidectomy, surgeons typically leave normal-appearing parathyroid glands *in situ*. Given the lower penetrance of PHPT in these patients, only a few centers advocate for total parathyroidectomy and autotransplantation at the time of the initial thyroid surgery.[76]

HPT–jaw tumor (HPTJT) syndrome is a rare autosomal dominant disease resulting from mutations in the *CDC73/HRPT2* gene, with patients predisposed to PHPT, ossifying fibromas of the maxilla or mandible, cystic and neoplastic renal lesions, and hyperplastic and neoplastic uterine involvement.[77] PHPT occurs with the highest penetrance, affecting approximately 80% of patients. These cases generally present with apparent single-gland disease.[77] Importantly, the syndrome is associated with parathyroid carcinoma in approximately 15% of patients.[78] With this association, the surgeon must carefully consider an oncologic resection during operative exploration.[79]

Familial isolated HPT (FIHPT) has had an evolving description and associations over the last 85 years.[80] It is a condition of HPT not associated with other endocrine disorders. Although this has been actively studied, it is still unclear if a specific gene mutation is associated with this disease. Recent studies suggest that over 80% of families with FIHPT have no identifiable gene mutations; however, some families with FIHPT have shown germline mutations in *MEN1*, *CASR*, or *CDC73*. In small cohorts of those without any of the aforementioned mutations, whole-exome sequencing identified germline *GCM2* mutations.[80] FIHPT has an inheritance pattern consistent with autosomal dominant transmission. In the absence of an identifiable mutation, surgical management is the same as that for sporadic PHPT. If a genetic mutation is identified, surgical management is tailored to the underlying disease.

Mutations in the *CASR* gene result in a number of calcium disorders. Inactivation mutations can lead to familial hypocalciuric hypercalcemia (FHH) if heterozygous, or neonatal severe PHPT (NSPHPT) if homozygous.[81,82] FHH results in lifelong elevated serum calcium levels with normal to mildly elevated PTH concentration and low renal calcium excretion. The hypercalcemia is generally mild and does not require treatment, and surgery is rarely indicated.[81] Occasionally, patients developed symptomatic PHPT and require surgical resection. NSPHPT is rare, presenting at birth or in early infancy with marked hypercalcemia, skeletal demineralization, and failure to thrive. If left untreated, it can be fatal.[81] These patients require hydration and urgent progression to surgery. Total parathyroidectomy with forearm parathyroid autotransplantation is the recommended surgical approach. Bisphosphonates, and increasingly cinacalcet, have been used with good effect with specific gene mutations, although generally as a temporizing measure.[83,84]

Parathyroid Carcinoma

Parathyroid carcinoma is a rare malignancy affecting less than 1% of those presenting with PHPT and accounting for 0.005% of all cancers in the United States.[85,86] Nearly all parathyroid carcinomas present with functional tumors and symptoms and signs of significant hypercalcemia. This diagnosis is suspected when significant preoperative elevation of calcium and PTH levels are noted.[86] Of those with parathyroid carcinoma, 30% to 76% have a palpable cervical mass on physical exam.[87] Although the majority are sporadic, parathyroid carcinomas can be associated with familial syndromes, HPTJT, MEN1, MEN2A, and FIHPT.[85] In apparent sporadic cases, inactivation of the *CDC73* gene has been identified in up to 70% of cases of parathyroid carcinoma, one-third of which are germline.

During surgery, parathyroid carcinoma often manifests as an enlarged, firm mass, adherent to surrounding structures, and is grey or white in color.[85] The optimal surgical approach remains *en bloc* oncologic resection with the ipsilateral thyroid lobe and other adherent structures that can be sacrificed for the best chance of cure.[88] Regional lymph node involvement occurs in only 10% of cases, and a careful exploration of the ipsilateral central neck and resection of abnormal-appearing or pathologically involved lymph nodes is recommended. Although still under investigation, prophylactic ipsilateral central or lateral neck dissections have not shown a survival benefit.[89,90] Resection of the ipsilateral parathyroid gland is also considered to clear all parathyroid tissue from the affected side.

Local recurrence rates vary greatly, ranging from 33% to 78%; however, over 75% of these patients had standard parathyroidectomy at the initial operation, and thus may not have had adequate resection.[89-91] Although locoregional disease is more common, the lungs and liver are the most common sites for distant metastasis. Surgery in cases with distant disease is often debulking to reduce tumor burden and relieve symptoms; rarely is it curative (Fig. 56.12). The overall survival rates, however, are generally good, with 5-year survival rates ranging from 76% to 85% and 10-year rates ranging from 49% to 77%. In cases of complete tumor resection at the initial operation, these rates are 90% and 67.5%, respectively.[90,92,93]

KEY POINTS: Parathyroid Carcinoma

- Parathyroid carcinoma is best managed at the initial operation.
- Suspected when preoperative calcium and parathyroid hormone are severely elevated.
- Intraoperatively often appears as an enlarged, firm, adherent grey/white structure.
- Oncologic resection with *en bloc* resection of the ipsilateral thyroid lobe and any other adherent resectable structures offers the best chance of cure.
- When suspicious, avoiding capsule disruption can prevent seeding of malignant parathyroid cells.

Pediatric Parathyroid Surgery

In the pediatric population, PHPT is rare, affecting two to five per 100,000 children; thus, the literature is comparatively limited.[94] Although the incidence is less, it is more likely to be clinically significant.[95,96] Most high-volume institutional studies have only a few pediatric cases to evaluate. A 2013 literature review of English-language studies identified 230 reported cases of pediatric PHPT since 1987 and demonstrated etiologies proportionally similar to adults. Single adenomas accounted for 80% of cases, multigland hyperplasia for 16.5%, and double adenomas for 0.9%. This population also has a higher incidence of hereditary disease, and half of the multigland hyperplasia patients were attributed to MEN1, MEN 2A, or familial non-MEN hyperparathyroidism.[97]

Presentation in pediatric patients varies, as serum calcium is not routinely checked in children; therefore, asymptomatic PHPT is not often diagnosed. Children can present with severe hypercalcemic symptoms such as hypotonia, poor feeding, vomiting, constipation, abdominal pain, lethargy, failure to thrive, polyuria, dehydration, and seizures.[98] Furthermore, likely because of the severity of hypercalcemia at the time of diagnosis, children are more likely to present with end-organ damage, such as nephrocalcinosis, nephrolithiasis, pancreatitis, or bone disease.[99] Studies estimate that 77% to 94% of pediatric patients are symptomatic at the time of diagnosis, and that 61% have major signs and symptoms, including 42% with nephrolithiasis, 27% with bone disease, and 3% with pancreatitis.[100,101]

Despite the severity of symptoms, similar to adults, the majority of sporadic pediatric PHPT cases are because of single adenomas. As such, the operative approach is similar to that for adult cases, with preoperative imaging for localization and surgical planning and intraoperative adjuncts including a PTH assay to determine the extent of surgery necessary. In cases with known or suspected familial syndromes, SHPT, or THPT, presentation at a very young age, or other suspicion of multigland disease, four-gland exploration may be required, but otherwise, local exploration is usually sufficient. Preoperative imaging modalities in this population relies on ultrasonography and technetium-99m-sestamibi, with MRI and 4D CT reserved for cases in which other modalities have failed to localize.[97,101] 4D CT utilization should be minimized, as it is associated with a greater radiation dose to the thyroid than sestamibi, even with low-dose CT imaging.

Although the literature is limited, several studies suggest that pediatric image-guided MIP results in similar cure rates to those reported in adults, at 92% to 100%.[94,102-106] Ectopic gland incidence is higher in the pediatric population, with a recent multiinstitutional series estimating 25% ectopic adenomas, and prior reported rates ranging from

10% to 37%.[94,104,105] As in the adult patient, with intraoperative PTH measurement, a reduction of levels to less than 50% of baseline and into the normal range is used as an indication of intraoperative biochemical cure.[106]

Familial forms of hyperparathyroidism in the pediatric population are associated with a higher risk of recurrence, because any parathyroid tissue is left *in situ* is genetically abnormal, resulting in a recurrence rate of 10% to 30%.[103] The goals of treatment are to achieve and maintain eucalcemia for the longest period, avoid permanent hypoparathyroidism, and facilitate future surgery for recurrent disease.[79,107] In the pediatric population, genetic multigland disease has two main surgical options: subtotal resection leaving a small marked remnant *in situ* or total parathyroidectomy with autotransplantation of parathyroid tissue into the forearm. The reimplanted tissue is marked with metallic clips to facilitate future exploration. The surgical approach can be based upon pubertal status. Four-gland total parathyroidectomy with autotransplantation may be performed in the postpubertal population. This is associated with at least a 3- to 4-week period of hypoparathyroidism during which the reimplanted tissue is revascularized, and there is a 25% to 50% risk of permanent hypoparathyroidism.[105] In the prepubertal population, it is thought to be advantageous to leave approximately 30 to 50 mg of parathyroid tissue *in situ* to avoid the risk of permanent hypoparathyroidism.

Compared with the adult population, children have higher rates of general and endocrine-specific complications following parathyroidectomy.[108] Database studies report rates of temporary and permanent hypocalcemia of 56% and 4%, respectively.[94] One contribution to the significant difference in intraoperative and postoperative complications is the level of experience of the surgeon.[57,109] Procedures performed by high-volume surgeons are associated with shorter lengths of stay, lower costs, and fewer complications compared with those performed by low-volume surgeons. Because PHPT is rare in the pediatric population, referral to a high-volume endocrine center for collaboration between pediatric and endocrine surgeons is strongly recommended for this group.[106,109]

Hyperparathyroidism in Pregnancy

The majority of published data regarding PHPT in pregnancy consist of case reports or small case series with limited power and high potential for bias.[110] As such, consensus multidisciplinary guidelines for evaluation and treatment have not explicitly addressed this population. PHPT in pregnancy occurs with an incidence of 0.15% to 1.4%; however, the risks to the mother and fetus are significant.[111] The physiologic changes that occur with pregnancy, including hypoalbuminemia, increased glomerular filtration rate, calcium transport across the placenta, and decreased PTH-mediated bone resorption from estrogen inhibition, coupled with high fetal calcium requirements, can mask or delay the diagnosis.[110,111] Additionally, many early symptoms may be dismissed because of the pregnancy, including fatigue, lethargy, and weakness.[110,111] Maternal complications such as nephrolithiasis, hyperemesis, preeclampsia, miscarriage, polyhydramnios, hypercalcemic crisis, and pancreatitis occur in as many as 67% of untreated patients.[110-112] Fetal or neonatal complications occur in up to 80% of cases in which the mother goes untreated, including intrauterine growth retardation, low birth weight, preterm delivery, intrauterine fetal demise, or postpartum neonatal hypocalcemic tetany.[110-112]

Management of PHPT in pregnancy must take into consideration the effect of treatment on the fetus. Furthermore, the risk of continued hypercalcemia and hyperparathormonemia to the patient and fetus must be deliberated, in conjunction with patient symptoms, prior obstetric history, and gestational age of the fetus when determining management strategy. Medical treatment is an option, consisting of low calcium diet and oral or IV hydration, occasionally with added diuretics, oral phosphates, and vitamin D supplementation. Bisphosphonates are contraindicated in pregnancy because they can affect fetal skeletal development. Cinacalcet has been advocated for use in these patients; however, there are insufficient safety data with regards to effects on the fetus.[110] Calcitonin is not known to cross the placental barrier; however, it is short-acting and therefore unlikely to provide a sustained benefit.[110] Alternatively, parathyroidectomy is the definitive treatment for PHPT in pregnancy. Surgery is recommended when the serum calcium is greater than 11 mg/dL (2.75 mmol/L), especially in those with previous loss of pregnancy.[111] It should also be considered in those with less severe hypercalcemia, specifically because of the complications noted with untreated disease. With surgery, patients can avoid potential harmful medications and the long-term maternal and fetal effects of hypercalcemia and hyperparathormonemia.[110] Following treatment, these patients have lower rates of preeclampsia and preterm labor compared with those managed medically.[113]

Similarly to the general population, PHPT in the pregnant population is caused by a solitary parathyroid adenoma in approximately 85% of cases.[111] The surgical approach is still dependent on preoperative localization. Imaging in this patient population is limited to ultrasound and MRI. Sestamibi scans were considered contraindicated in pregnancy; however, some authors suggest that they can be used selectively by utilizing techniques to reduce fetal irradiation.[111] 4D CT should be avoided because of the risk of radiation exposure to the fetus. If imaging can localize a candidate lesion, a focal exploration with intraoperative PTH measurement without general anesthesia can be performed.[111] If imaging is unable to identify a candidate lesion, bilateral cervical exploration under general anesthesia is still a safe option.

The timing to proceed to surgery is still debated. For asymptomatic patients with minimal serum calcium elevation, surgery may be delayed until the postpartum period. Concern for fetal outcomes with surgical intervention is the reasoning behind opting for medical treatment during pregnancy.[111] Additionally, limitations on localizing imaging studies further discourage surgical intervention. Finally, there are additional risks during pregnancy related to general anesthesia. In cases where it is deemed necessary to proceed with surgery during pregnancy, because of incomplete organogenesis in the first trimester and the possibility of inducing preterm labor during the third trimester, parathyroidectomy is preferably performed in the second trimester.[113] In more severe cases, when medical management is unsuccessful or there is evidence of maternal or fetal complications, surgery can be performed safely regardless of gestational age. Reviews of medical compared with surgical treatment during pregnancy show increases in both maternal complications and neonatal tetany in those managed medically.[111] Following surgical intervention, the rate of neonatal complication was lower than in those who had medical treatment alone.[111,113]

SECONDARY HYPERPARATHYROIDISM

In SHPT, chronic hypocalcemia results in persistent stimulation of the parathyroid glands, leading to multigland hypertrophy. Most commonly, it is seen with end-stage renal failure (uremic hyperparathyroidism), but it is also present with certain bone and metabolic conditions such as malnutrition, malabsorption, vitamin D deficiency, chronic cholestasis, and with use of lithium.

In the renal failure population, patients generally have low serum calcium and 1,25-hydroxy-vitamin D levels, and significantly elevated serum phosphate and intact PTH levels. Although approximately 75% of the renal failure population have biochemically evident SHPT, the Healthcare Cost and Utilization Project's Nationwide Inpatient Sample estimates that, overall, 5.4/1000 renal dialysis patients require parathyroidectomy each year.[114] This risk increases with the duration of dialysis treatment, to 15% of patients after 10 years of therapy and 38% after 20 years.[115] Patients are initially managed medically, with calcitriol and calcimimetics, reserving surgery for those who fail medical therapy. Surgical indications for uremic hyperparathyroidism include uncontrollable hyperphosphatemia, worsening osteoporosis with bone pain and fractures, development of bone erosions or osteitis fibrosa cystica, and calciphylaxis.[116]

With vitamin D deficiency-associated SHPT, diminished calcium absorption in the gastrointestinal system results in hypocalcemia, causing chronically elevated PTH levels. Although occurring widely, it is common in the obese population. Unique to this population, bariatric surgery with subsequent malabsoprtive syndromes can exacerbate vitamin D deficiency and resultant SHPT in as many as 20% to 30% of patients. This exacerbation occasionally progresses to a level at which patients require surgical intervention.[117] As the prevalence of bariatric surgery increases, this phenomenon is seen with increasing frequency. Wei et al. described SHPT in 21% of the preoperative obese cohort, in 35% 1 year following bariatric surgery, and in 63% 5 years postoperatively.[117]

The pathophysiology of SHPT results in multigland disease. Accordingly, the surgical management generally consists of either subtotal parathyroidectomy or total parathyroidectomy with parathyroid autotransplantation. Total parathyroidectomy without autotransplantation is undesirable because of resulting severe hypoparathyroidism.[118] There do not appear to be significant differences in complication rates between these two operations; however, total parathyroidectomy is associated with increased length of stay and increased readmission rates compared with subtotal parathyroidectomy.[119] Trends suggest that subtotal parathyroidectomy is the preferred approach in the United States, whereas total parathyroidectomy with autotransplantation is preferred in Japan; however, there are additional factors that must be considered.[116] Patients unlikely to progress to renal transplantation will continue to have lifelong stimulation of any remaining parathyroid tissue; thus, total parathyroidectomy with autotransplantation into the forearm may be preferable to avoid the need for cervical reoperation. In those who may be candidates for renal transplant, a subtotal parathyroidectomy, with preservation of approximately 30 mg of parathyroid tissue *in situ*, is preferable, as it is sufficient to provide normal parathyroid function. Additionally, by leaving only a small amount of parathyroid tissue in a single location in the neck, should cervical reoperation be required, it can be expedited. Following autotransplantation of parathyroid tissue, it can take 12 to 18 weeks for circulating PTH levels to return to normal, and these patients may have profound hypoparathyroidism and hypocalcemia that is exacerbated by renal osteodystrophy and hungry bone syndrome.

Irrespective of the surgical approach, 15% to 30% of SHPT patients have supernumerary glands and need a thorough parathyroid exploration for optimal results.[120] Transcervical thymectomy should be a standard part of surgical management of SHPT because of the high incidence of supernumerary glands in the thyrothymic ligament and thymus. If not resected, these sites can cause persistent disease and, with chronic stimulation, grow and result in disease recurrence. One study found that over 28% of uremic hyperparathyroid patients undergoing reoperative parathyroidectomy had an intrathymic parathyroid gland removed at reoperation, suggesting that this could have been prevented had thymectomy been performed at the initial operation.[121]

Following surgery, these patients require meticulous management because they are prone to significant postoperative hypocalcemia, requiring inpatient admission for several days with oral and IV calcium supplementation and calcitriol. Because most have lived with chronic hypocalcemia, they often do not exhibit overt symptoms until their calcium levels are considerably abnormal. Accordingly, it is extremely important to have an experienced team for management to prevent serious, potentially life-threatening, hypocalcemia.

Preoperative imaging in these cases is controversial. Contrary to PHPT, in SHPT four-gland exploration should always be performed. Some advocate for no preoperative imaging studies, as gland localization to limit surgery is unnecessary, given known multigland disease. However, sestamibi or CT imaging may be able to identify ectopic or supernumerary glands that could be missed with standard exploration. Additionally, an ultrasound would screen for concomitant thyroid pathology that should be addressed simultaneously.

The use of intraoperative PTH measurement during these cases is also controversial, but not without benefit. Because PTH is renally cleared, and these patients often have a profoundly increased baseline PTH, intraoperative drop in PTH to the normal range generally does not occur quickly. However, analysis of the changes can still be used to predict cure. Although there is no consensus, several studies suggest that a decrease in intraoperative PTH levels from baseline by 80% or more at 20 minutes following completion of either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation predicts cure in long-term follow-up.[122-124]

TERTIARY HYPERPARATHYROIDISM

THPT is a condition in which prolonged stimulation from SHPT results in autonomous parathyroid hyperfunction. It most commonly occurs in patients with uremic hyperparathyroidism and in end-stage renal patients following renal transplantation. Although mild hypercalcemia may be present following renal transplantation, it most commonly resolves within the first year. Persistence beyond 2 years, significant hypercalcemia, or the development of hypercalcemia following a normocalcemic posttransplant period is indicative of this disease.[118,125-127]

Surgery is indicated in the vast majority of THPT patients because of the risk of hypercalcemic toxicity to the renal transplant and severe bone disease. Because of the mechanism of development, four-gland exploration should be performed because all parathyroid glands will be abnormal. Subtotal parathyroidectomy is the procedure of choice, although some opt for a more limited image-guided parathyroidectomy.[118,125,126] Similar to SHPT, if bilateral exploration is performed, imaging for localization is not necessary; however, it can be useful in the setting of ectopic glands. Intraoperative PTH measurement is not necessary but can be used to confirm intraoperative cure and predict long-term cure.[122,128,129]

KEY POINTS: Secondary and Tertiary Hyperparathyroidism

- Secondary hyperparathyroidism (SHPT) is attributed to chronic hypocalcemia causing persistent parathyroid stimulation.
- Tertiary hyperparathyroidism (THPT) is a result of prolonged SHPT resulting in autonomous parathyroid hyperfunction.
- There are several causes of SHPT and THPT; end-stage renal disease is the most common.
- Multigland hyperplasia must be anticipated and appropriately addressed during surgery.

COVID-19 AND PARATHYROID SURGERY

First identified as a pneumonia epidemic spreading through Wuhan, the capital of the Hubei province China, the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) is a novel RNA coronavirus. It rapidly spread across China, to Italy and other European countries, then to the United States and throughout the world.[130] It was named coronavirus disease 2019 (COVID-19) by the World Health Organization and declared a pandemic in early 2020 owing to the rapidity and degree of its spread. There is significant variability in presentation, from asymptomatic carriers to severe interstitial pneumonia and acute respiratory distress syndrome with multiorgan failure leading to severe acute respiratory failure and death.[130] Although this disease is still being studied, it has had a significant effect on the medical system and will continue to do so for an indeterminate period of time.[131] As such, it is pertinent to examine how this disease affects operative intervention for HPT.

COVID-19 is generally spread through respiratory droplets, from direct, indirect, or close contact with infected persons, and medical procedures can lead to aerosol formation and viral dissemination, putting providers and patients at risk for infection.[132] Procedures involving instrumentation of the oropharyngeal, nasopharyngeal, and respiratory mucosa are high risk for aerosolization.[132,133] Additionally, those with active infections are at higher risk for postoperative complications. As such, it is important to consider infection status when planning surgery.[134]

Because of the fraction of patients with COVID-19 that become profoundly ill, regions fluctuate in local disease burden and need for hospitalization. When infection rates peak, cities have reported hospitals and intensive care units full to overflowing with COVID-19 patients, as well as cessation of many other inpatient services, including nonemergency surgeries, owing to lack of available space, staff, and equipment.[133,135] The vast majority of parathyroid surgery is elective. As such, depending on the local disease burden and hospital capacity, the majority of these procedures may be delayed until the resources are available.

When resources are available to proceed with surgery, for the safety of the patient, care providers, and others in the hospital, it is now recommended to test for COVID-19 preoperatively.[135] If the patient is asymptomatic and the test is negative, proceed with surgery as per hospital guidelines. However, if the patient is symptomatic or the test is positive, additional consideration is necessary. In emergent cases that cannot be delayed, providers should take additional precautions for personal protection, but in most cases, surgery can be deferred until it is safe to proceed, reducing the operative risk and potential for virus transmission.[131,134,135] Both direct and indirect laryngoscopy for vocal cord evaluation should also be avoided without confirmation of COVID-19 status for provider protection.

SUMMARY

Hyperparathyroidism encompasses a complex collection of diseases requiring careful diagnosis and, when surgery is indicated, meticulous, thoughtful, surgical management. When indicated, parathyroidectomy is curative in the vast majority of patients, increasingly so when managed by high-volume centers/surgeons. Preoperative imaging and intraoperative adjuncts allow for minimally-invasive approaches. Patients with persistent and recurrent disease, HPT with a genetic basis, or parathyroid carcinoma and the pediatric patient population represent the most complex surgical patients and require additional consideration and expertise in management.

  Sporadic Pseudohypoparathyroidism Type-1B, 984
Pseudohypoparathyroidism Type-II, 984
Acrodysostosis With Hormonal Resistance, 985
Treatment, 986
Summary, 986

In 1942, Albright et al.[1] described a group of patients who displayed certain physical features, including obesity, short stature, brachydactyly, and cognitive impairment, combined with hypocalcemia and hyperphosphatemia. In these patients, exogenous, biologically active parathyroid hormone (PTH) extracts failed to result in a full phosphaturic response; hence, the term pseudohypoparathyroidism (PHP) was introduced, indicating that hypocalcemia and hyperparathyroidism in these patients resulted from target-organ resistance to, rather than deficiency of, PTH. Consistent with resistance to the actions of this hormone, it was later shown that patients affected by PHP have elevated concentrations of immunoreactive PTH.[2] Subsequently, it was also shown that some patients affected by PHP have resistance toward other hormones; however, PTH resistance is the most prominent feature of the disease.

The primary site of PTH resistance in PHP is the renal proximal tubule, as the actions of PTH in bone and the distal tubule appear normal.[3,4] Patients with PHP have reduced or inappropriately normal serum concentrations of 1,25-dihydroxyvitamin D (1,25(OH)$_2$D), which is the main cause of hypocalcemia.[5,6] Both low serum 1,25(OH)$_2$D and hyperphosphatemia are the direct results of PTH resistance at the proximal tubule. Hyperphosphatemia is typically worsened by the elevation of PTH in the circulation and the absence of resistance to the bone resorptive actions of this hormone, which leads to the release not only of calcium, but also of phosphate. Besides these unimpaired actions of PTH on bone, as well as unimpaired PTH-dependent calcium reabsorption in the renal distal tubule,[7,8] elevated serum PTH levels can prevent symptomatic hypocalcemia in PHP patients for extended periods of time. However, at some point in their lives, most patients manifest hypocalcemia and, therefore, present with associated clinical findings.

DIAGNOSIS AND PROGRESSION OF PARATHYROID HORMONE RESISTANCE

PTH exerts its actions by binding to a seven transmembrane domain, G protein-coupled receptor (the PTH/PTH-related protein receptor, PTHR1).[9] Although PTHR1 can couple to several different G proteins,[10] most PTH actions are mediated primarily through the stimulatory G protein, which acts on adenylyl cyclase, thereby increasing the formation of intracellular second messenger cyclic adenosine monophosphate (cAMP). PTH-induced cAMP formation is used as an important indicator of renal tubular PTH function, as most PHP patients display an inadequate or absent increase of urinary cAMP in response to exogenous, biologically active PTH (Fig. 57.1).[11] In fact, assessing the nephrogenous cAMP response to exogenously administered PTH is used as a test for establishing the diagnosis of PHP, and is more sensitive than measuring the increase in urinary phosphate excretion used in the original Ellsworth–Howard test. However, currently used high-sensitivity PTH assays often suffice to make the diagnosis when serum PTH is elevated in the presence of hypocalcemia and hyperphosphatemia. Nonetheless, depending on the nature of the nephrogenous response to exogenous PTH, PHP is subdivided into two main types. PHP type-I (PHP1) is defined by blunted urinary excretion of both cAMP and phosphate, and PHP type-II (PHP2) by blunted urinary excretion of phosphate only.[1,11]

Signs and symptoms of decreased serum calcium levels often reflect secondary prolongation of the QT interval on electrocardiogram and increased neuromuscular excitability leading to Trousseau's and Chvostek's sign, as well as laryngospasm. Although the most common manifestations of hypocalcemia include muscle tetany and spasms, findings vary markedly among patients. In more severe cases,

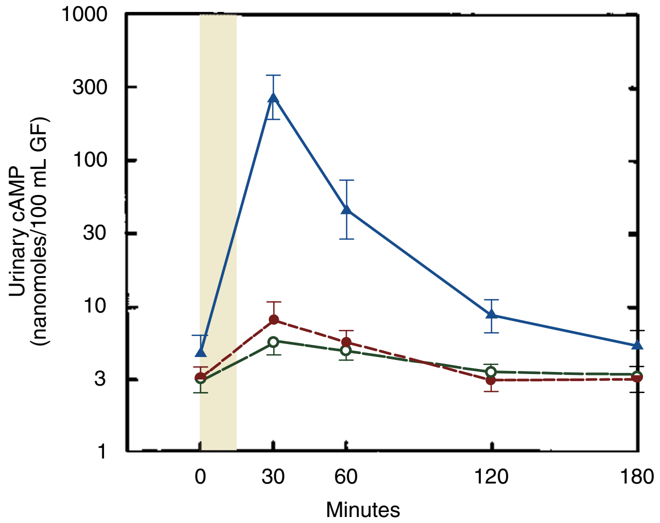

Fig. 57.1 Time-Course of Urinary Cyclic Adenosine Monophosphate (cAMP) Levels in Response to Parathyroid Hormone (PTH) Infusion. Upon injection of PTH, normal subjects (triangles) exhibit a 50- to 100-fold peak over the basal, while patients with pseudohypoparathyroidism type-Ia (open circles) or pseudohypoparathyroidism type-Ib (solid circles) demonstrate a blunted response. (Modified from Levine MA, Jap TS, Mauseth RS, et al. Activity of the stimulatory guanine nucleotide-binding protein is reduced in erythrocytes from patients with pseudohypoparathyroidism and pseudopseudohypoparathyroidism: Biochemical, endocrine, and genetic analysis of Albright's hereditary osteodystrophy in six kindreds. *J Clin Endocrinol Metab.* 1986;62:497–502.)

patients present with seizures. Other neurological symptoms can also arise from hypocalcemia, and some patients with PHP can initially be diagnosed with movement disorders.[12] In one report, two sisters with PHP1B (see later) presented with paroxysmal kinesigenic choreoathetosis, and the diagnosis of PTH resistance in one sister was made after approximately 4 years of oral antiepileptic treatment, when biochemical evaluation and genetic testing was performed.[13] Some patients presenting with seizures demonstrate epileptiform electroencephalogram changes, and, because this activity typically responds to antiepileptic treatment, the diagnosis of PHP can be delayed.[12] As another complication of the changes in serum calcium and phosphorous, brain imaging studies frequently show intracranial calcifications in PHP patients.[12]

PHP is a congenital disorder, but only few reports describe findings consistent with PTH resistance during the neonatal period.[14,15] Clinical manifestation of hypocalcemia typically occurs only later in childhood, suggesting that PTH resistance and the resultant changes in serum calcium and phosphorous develop gradually.[16-18] In a longitudinal study of a child with PHP1A (see later), cAMP response to PTH was found to be normal at age 3 months, whereas it was blunted at age 2.6 years.[8] In another PHP1A case, a gradual decline of serum calcium, preceded by increasing serum phosphorous and PTH levels, was demonstrated.[16] In addition, a PHP1B patient diagnosed by genetic analysis (see later) at birth was shown to have normal serum PTH levels until age 18 months, when an elevation of PTH was first detected despite normal serum calcium and phosphorous.[17] It thus appears that PTH responses are intact during the early postnatal period despite the existence of the molecular defect underlying PHP. The mechanisms that allow normal PTH signaling during this developmental stage remain unknown.

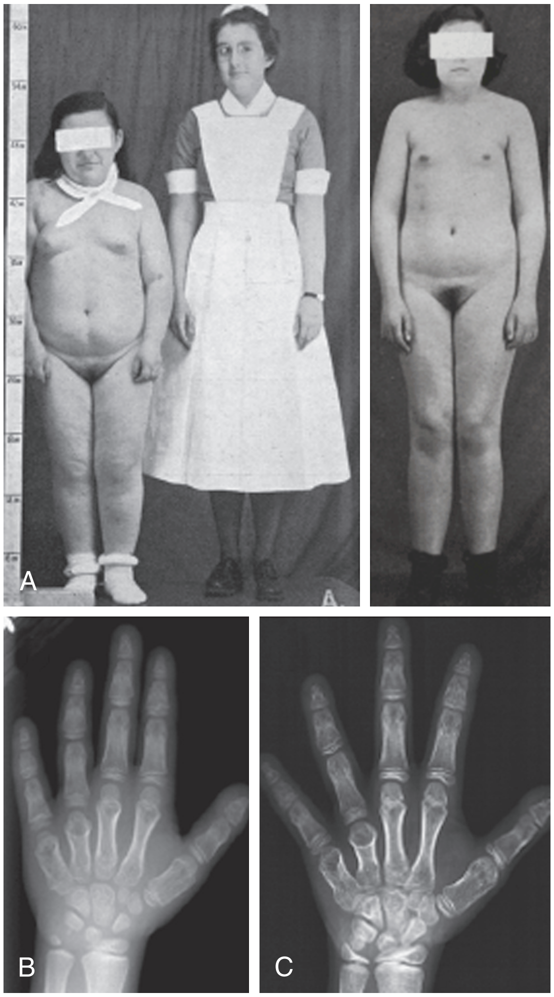

Fig. 57.2 Albright's hereditary osteodystrophy (AHO). **A,** Short stature and obesity are among the typical features of AHO. **B,** Hand radiograph of a child with AHO demonstrating short fourth and fifth metacarpals at age 5 11/12 years. **C,** The same patient's hand radiograph at age 8 10/12 years. (**A** Modified from Albright F, Burnett CH, Smith PH, et al. Pseudohypoparathyroidism — an example of "Seabright-Bantam syndrome". *Endocrinology.* 1942;30:922–932.)

PSEUDOHYPOPARATHYROIDISM TYPE-Ia

Of the two main PHP types, PHP1 is much more common. Various clinical variants of PHP1 have been described based on the presence or absence of clinical manifestations that coexist with PTH resistance, diminished stimulatory G protein activity in easily accessible cells, and silenced expression of the α-subunit of the stimulatory G protein (Gsα) from the *GNAS* complex gene (Table 57.1).

Albright's Hereditary Osteodystrophy and Multihormone Resistance

As described originally by Albright et al.,[1] PHP1 patients often exhibit characteristic physical features that may include obesity, round facies, short stature, brachydactyly, ectopic ossification, and intellectual disability (Fig. 57.2). These features are termed Albright's hereditary osteodystrophy (AHO) and occur primarily in those PHP patients, who are now classified as having PHP type-Ia (PHP1A). The brachydactyly observed in patients with AHO typically involves the metacarpal and/or metatarsal bones, and thus the pattern of shortening of the hand

TABLE 57.1 **Clinical and molecular features of the different PHP forms**

	PTH-resistance	Additional hormone resistance	Typical AHO features	Genetic defect
PHP1A/1C	Yes	Yes	Yes	*GNAS* mutations involving Gsα coding exons
PPHP	No	No	Yes	*GNAS* mutations involving Gsα coding exons
POH[a]	No	No	No	*GNAS* mutations involving Gsα coding exons
PHP1B	Yes	Some cases	No[b]	Microdeletions, duplications, inversions affecting *GNAS* imprinting, or patUPD20q[c]
PHP2	Yes	No	No	Unknown[d]

[b] Some recent studies have demonstrated co-existence of AHO features and *GNAS* imprinting defects.

[c] Paternal uniparental disomy of chromosome 20q

[d] Mutations of *PRKAR1A*, *PDE4D*, or *PDE3A* are responsible for some variants of PHP2 associated with skeletal findings.

bones differs from other disorders with brachydactyly, such as familial brachydactyly and Turner's syndrome.[19] Because of shortened metacarpals, dimpling over the knuckles of a clenched fist (Archibald sign) is often observed.[20] The shortening of the distal phalanx of the thumb, however, is the most common skeletal abnormality (called "murderer's" or "potter's" thumb), and some patients have shortening of all digits.[21] Intellectual disability is mild, often presenting as cognitive defects. It is possible that the cause of cognitive impairment is the deficiency of Gsα signaling in the brain. Although hypocalcemia and/or hypothyroidism may also play a role in this phenotype, correction of these biochemical defects typically does not prevent it. There is remarkable patient-to-patient variability in AHO, even among patients that carry the same genetic mutation and belong to the same family (see later for discussion of the underlying genetic defect). Some patients may exhibit a single AHO feature only, such as obesity, while others may present with multiple different AHO features.[22] Furthermore, the severity of each feature differs vastly among the patients. In addition, individual AHO features are not unique to PHP, as they can be observed in other unrelated disorders, for example, acrodysostosis caused by *PDE4D*, *PDE3A*, *PTHLH*, or *PRKAR1A* mutations[23–26] or Brachydactyly-Mental Retardation Syndrome caused by *HDAC4* mutations.[27] The variable expressivity and the lack of specificity of individual features can make the AHO diagnosis challenging. Although the coexistence of hormone resistance in PHP1A patients is often helpful, it can also be misleading. This is particularly important in differential diagnosis of different PHP forms characterized by the presence of AHO features alone or hormone resistance alone (see later).

In addition to having PTH resistance and AHO, patients with PHP1A show clinical evidence that is consistent with target-organ resistance to other hormones. The most common additional hormone resistance involves the actions of thyroid-stimulating hormone (TSH), leading to hypothyroidism.[28,29] In fact, unlike PTH resistance, which typically develops later in life, TSH resistance can be present at birth.[30,31] Resistance towards gonadotropins and growth hormone–releasing factor has been reported,[32,33] whereas resistance toward other peptide hormones that also mediate their actions through Gsα-coupled receptors, such as vasopressin, calcitonin, or adrenocorticotropic hormone, does not appear to become clinically overt[12].

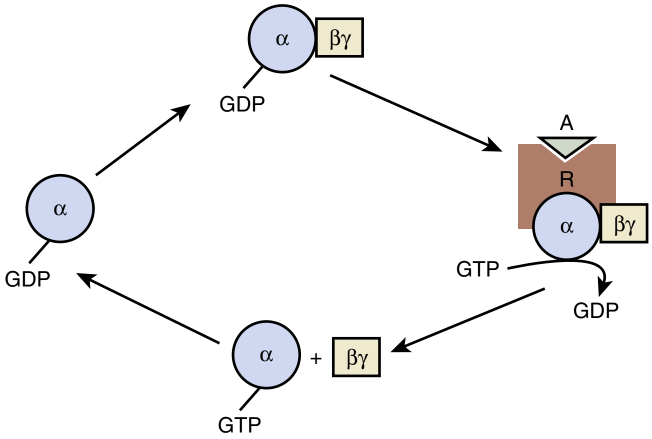

Fig. 57.3 Heterotrimeric G protein activation cycle. The heterotrimeric complex is assembled at the basal state, with the α-subunit being associated with a GDP molecule. Upon binding of an agonist (A) to its Gs-coupled receptor (R), the GDP molecule bound to the α-subunit is replaced with a GTP molecule, that is, the receptor acts as a guanine nucleotide exchange factor for the α-subunit. The GTP-bound form of the α-subunit dissociates from the βγ subunits and thereby stimulates its downstream effectors, which, in the case of Gsα, includes adenylyl cyclase. Note that the free Gβγ dimer can also stimulate different downstream effectors. The intrinsice GTP hydrolase activity of the α-subunit converts the GTP into GDP, resulting in the reassociation of the heterotrimer and, thereby, termination of effector stimulation.

Coding Gsα Mutations as the Underlying Cause of Pseudohypoparathyroidism Type-Ia

The genetic mutation causing PHP1A involves Gsα-coding *GNAS* exons.[34,35] A protein that is essential for the actions of many hormones, Gsα primarily mediates agonist-induced generation of intracellular cAMP. Activation of a stimulatory G protein coupled receptor by an agonist, such as PTH, leads to a GDP-GTP exchange on Gsα, causing dissociation of the latter from Gβγ subunits (Fig. 57.3). This allows both Gsα and Gβγ to stimulate their respective effectors. In its GTP-bound state, Gsα can directly activate several different effectors, such as Src tyrosine kinase,[36] and certain calcium channels.[37,38] Apart from these effectors, however, adenylyl cyclase is by far the most ubiquitous and the most extensively investigated effector molecule stimulated by Gsα. An integral membrane protein, adenylyl cyclase catalyzes the synthesis of the ubiquitous second messenger cAMP, which then triggers various cell-specific responses. The activation of adenylyl cyclase and other effectors by Gsα is regulated by the intrinsic GTP hydrolase (GTPase) activity of Gsα. Conversion of GTP into GDP results in the reassembly of the G protein heterotrimer, thereby preventing further effector stimulation (Fig. 57.3).

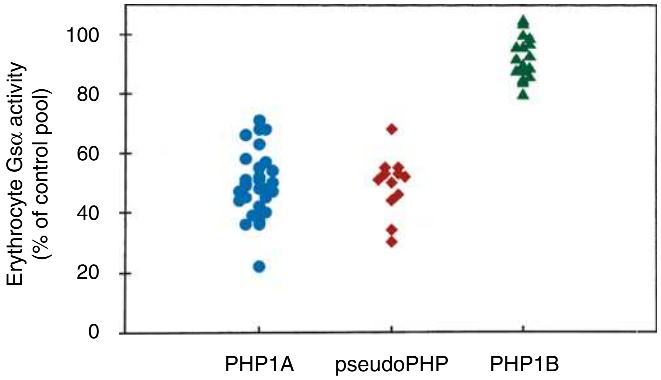

Fig. 57.4 Gsα erythrocyte activity in pseudohypoparathyroidism type-1a (PHP1A), pseudopseudohypoparathyroidism (*pseudo PHP*), and pseudohypoparathyroidism type-1b (PHP1B) patients. The measurement is conducted by complementation of patient-derived erythrocyte membranes with membranes from S49cyc- lymphoma cells, which genetically lack Gsα but retain all other components necessary for hormone-activated adenylyl cyclase response. (Modified from Levine M. Hypoparathyroidism and pseudohypoparathyroidism. In: DeGroot LJ, Jameson J, eds. *Endocrinology.* Philadelphia: W.B. Saunders; 2000:1133–1153.)

Mutations identified in PHP1A patients are heterozygous and scattered throughout all the 13 *GNAS* exons encoding Gsα and the intervening sequences, including missense and nonsense amino acid changes, insertions/deletions that cause frameshifts, and nucleotide alterations that disrupt pre-mRNA splicing. Constitutional deletions of the chromosomal arm containing *GNAS* have also been identified.[39] Among the many different inactivating *GNAS* mutations, a 4-bp deletion in exon 7 has been identified in numerous families, representing a genetic "hot spot." An extensive list of these mutations can be found at Online Mendelian Inheritance in Man entry #139320 (https://www.omim.org) and other gene-specific databases, such as Leiden Open Variation Database, https://databases.lovd.nl/shared/genes/GNAS). Consistent with this mutational spectrum, Gsα level/activity is reduced by approximately 50% in easily accessible tissues from PHP1A patients, such as erythrocytes, skin fibroblasts, and platelets.[40,41] Deficiency of Gsα has also been demonstrated in renal membranes from a patient with PHP.[42] A complementation assay is typically used for examining Gsα activity, involving patient-derived erythrocyte membranes and membranes from turkey erythrocyte that lack endogenous Gsα (Fig. 57.4). Gsα hypofunction can also be detected in patient-derived platelets by using a functional test that examines the ability of prostaglandin E1 or prostacyclin to inhibit platelet aggregation.[43] The detection of reduced Gsα activity is important for the establishment of PHP1A diagnosis, particularly in cases where genetic analysis fails to reveal a *GNAS* mutation. Reduction of Gsα activity in PHP1A is consistent with the fact that PTH and the other hormones with impaired actions in this disorder act via cAMP-mediated signaling pathways.

PHP1C has been described as a distinct variant of PHP1A,[44] but the clinical and laboratory features of patients with PHP1C are identical to those with PHP1A, as they have both AHO and multihormone resistance. In contrast to PHP1A, however, biochemical assays demonstrate no reduction in Gsα activity in erythrocytes obtained from PHP1C patients, suggesting the absence of mutations within the *GNAS* gene. Nevertheless, recent molecular characterizations have revealed Gsα mutations at least in some PHP1C patients. However, the Gsα mutants show only impaired coupling to different G protein–coupled receptors, yet show normal Gsα activity in complementation assays that use nonhydrolyzable GTP analogs for stimulation of Gsα activity rather than a receptor agonist.[21,45] Thus, the mutant Gsα protein causing PHP1C allows basal cAMP formation but is unable to trigger an increase in response to hormones. Hence, at least some PHP1C cases are allelic variants of PHP1A. Although it remains possible that some patients who match the description of PHP1C develop hormone resistance and AHO because of a novel gene mutation that affects cAMP production without functionally impairing Gsα itself—for example, inactivating mutations affecting one of the adenylyl cyclases or activating mutations in one of the phosphodiesterases—it appears unlikely that such putative mutations affect only few G protein-coupled receptors and thus cause limited hormonal resistance as observed in PHP1A and PHP1C, but instead dictate the phenotype by the tissue-specificity of their expression levels.

THE COMPLEX *GNAS* LOCUS

The Alpha Subunit of the Stimulatory G Protein (Gsα)

GNAS is a complex locus giving rise to multiple different coding and noncoding transcripts that show monoallelic, parent-of-origin–specific expression profiles (Fig. 57.5). *GNAS* maps to the telomeric end of the long arm of chromosome 20 (20q13.2-20q13.3).[46-48] Gsα is encoded by 13 exons,[49] but, because of alternative pre-mRNA splicing, the Gsα transcript has several variants. The long and short Gsα variants (Gsα-L and Gsα-S, respectively) differ from each other by the inclusion or exclusion of exon 3[49-51]; these Gsα variants are typically detected as 52- and 45-kDa protein bands on Western blots. Showing further complexity, each Gsα form either includes or excludes a CAG trinucleotide (encoding serine) at the start of exon 4. Small, but potentially important, differences have been reported between the activities of Gsα-L and Gsα-S. For example, Gsα-L has been shown to display greater ability to mediate receptor signaling than Gsα-S when partially purified proteins from rabbit liver were examined,[52] although the opposite finding was reported upon the use of cultured pancreatic islet cells.[53] Furthermore, the GDP release rate from Gsα-L appears to be approximately 2-fold higher than that of Gsα-S,[54] and, accordingly, fusion proteins involving the β2-adrenergic receptor and Gsα-L have shown higher constitutive activity than those involving the receptor and Gsα-S.[55] Moreover, differences in the subcellular targeting of these two Gsα variants have been reported.[56-58] Currently, it remains unclear whether these differences translate into biologically significant effects, such as divergence in the variety of effectors and/or the efficiency of effector activation. Nonetheless, a single nucleotide insertion in exon 3 leading to frameshift and early termination has been recently identified in two siblings affected by a mild form of PHP1A.[59] The mildness of the phenotype is consistent with generation of one of the two main Gsα variants, that is, Gsα-S. It remains unknown whether this exon 3 mutation impairs agonist responses in an effector- and tissue-specific manner, and this possibility depends on the putative effector selectivity and relative expression levels of Gsα-L and Gsα-S in different tissues.

Imprinted Products of the *GNAS* Locus. Recent studies have revealed that *GNAS* gives rise to multiple additional gene products that show parent-of-origin–specific, monoallelic expression. Besides Gsα, at least two translated *GNAS* transcripts exist, using distinct upstream promoters and alternative first exons that splice onto exons 2 to 13 encoding Gsα. The most upstream promoter relative to the Gsα promoter drives expression of a neuroendocrine secretory protein with an apparent molecular mass of 55 kDa (NESP55).[60] The paternal *NESP55* promoter is methylated, and transcription occurs from the maternal allele.[61,62] In humans, NESP55 is encoded by a single exon, so that Gsα exons 2 to 13 comprise the 3' untranslated region.[61,62] Expressed in neuroendocrine tissues, the peripheral and central nervous system,

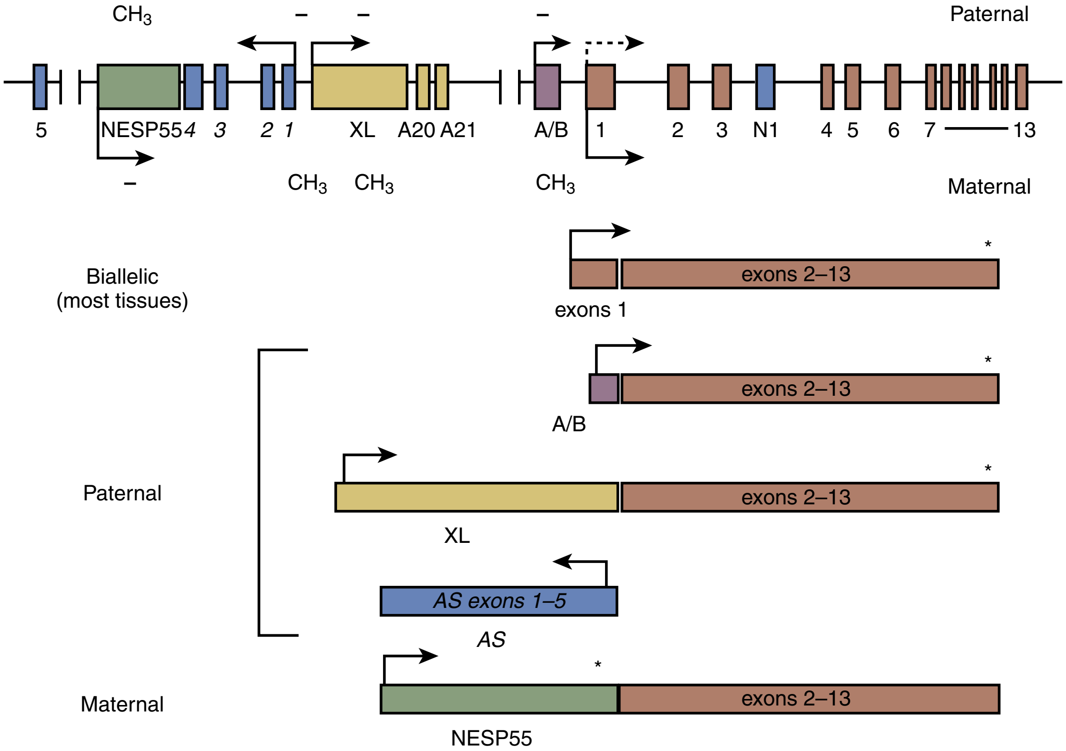

Fig. 57.5 The *GNAS* locus. The complex *GNAS* locus gives rise to multiple transcripts. Boxes and connecting lines indicate exons and introns, respectively. Arrows show the direction of transcription for each transcript. The main transcriptions derived from *GNAS* and the used exons are depicted as rectangles below the gene schematic. Gsα is biallelically expressed, except in a small number of tissues, including renal proximal tubules, thyroid, gonads, and pituitary, in which expression from the paternal allele is silenced (*dashed arrow*). XLαs, A/B, and antisense (*AS*) transcripts are derived from the paternal allele, and the NESP55 transcript from the maternal allele. Promoters of XLαs, A/B, antisense, and NESP55 transcripts are methylated on the silenced allele, as indicated by CH_3 (methylated CpGs) and - (unmethylated CpGs).

and some endocrine tissues,[60,63] NESP55 is a chromogranin-like protein associated with the constitutive secretory pathway.[64] Loss of the expression of NESP55 does not seem to have an overt clinical outcome in humans, as evidenced in patients with PHP1B (see later). However, its disruption in mice results in a subtle behavioral phenotype characterized by increased reactivity to novel environments.[65] Transcription from the *NESP55* promoter is likely to play a role in the regulation of *GNAS* imprinting (see later).

Another *GNAS* product is XLαs, which is expressed from the paternal allele.[62,66,67]. XLαs is expressed abundantly in various parts of the brain and neuroendocrine tissues, and its expression can be readily detected in a variety of other fetal and postnatal tissues.[68,69] XLαs also uses a distinct upstream promoter and a unique first exon that splices onto Gsα exons 2 to 13.[62,67] Unlike in *NESP55* transcript, however, the latter portion of the *XLαs* transcript is included in the translated product, resulting in a protein that is partially identical to Gsα.[66] Consistent with its structural similarity to Gsα, XLαs can mediate receptor-activated adenylyl cyclase stimulation in transfected cells and in transgenic mice.[70-72] In fact, it appears to be basally more potent than Gsα when expressed at levels comparable to the latter and is able to prolong PTH signaling in transfected cells.[73] However, the phenotype of mice with targeted ablation of paternal XLαs suggests that XLαs has unique, albeit as-yet-undefined, cellular functions. These mice show high early postnatal mortality because of poor adaptation to feeding and impairment in the glucose and energy metabolism,[74] in contrast to Gsα knockout mice, which to a large extent recapitulate findings in patients with PHP1A.[75,76] Findings from adult mice with disrupted XLαs expression indicate that this protein is a negative regulator of increased sympathetic nervous system activity in mice.[77] Recent studies have suggested novel cellular actions of XLαs, including the stimulation of PLC/PKC signaling and inhibition of clathrin-mediated endocytosis.[78,79]

The paternal *GNAS* allele also gives rise to two additional transcripts. From the sense strand originates the A/B transcript (also termed 1A or 1'), which, similar to NESP55 and XLαs, uses an upstream promoter and an alternative first exon (exon A/B) that splices onto Gsα exons 2 to 13.[80,81] Exon A/B does not comprise an in-frame translation initiation codon but, as demonstrated *in vitro*, the translation can be started through the use of an AUG located within exon 2, thereby giving rise to an N-terminally truncated protein that localizes to the plasma membrane when transiently expressed in cell lines.[81] Until recently, no evidence has supported the existence of an endogenous A/B protein, and therefore it was thought that the *A/B* transcript was a noncoding RNA. Endogenous A/B protein has recently been detected, however, in human fetal kidney by Western blot using an antibody against the C-terminal end of Gsα.[82] It remains possible that A/B has functions both as a protein and as a transcript regulating the expression within the *GNAS* locus (see later). Another paternal *GNAS* transcript is derived from the antisense strand.[83,84] The *GNAS* antisense transcript (*GNAS-AS1*), which is formed in humans by at least five primary exons that show multiple alternative splicing patterns,[83,85] is also considered to be noncoding. Data from mouse models indicate that *GNAS-AS1* plays a critical role in silencing the paternal *NESP55* promoter in *cis*.[86] The promoter of *GNAS-AS1* is immediately upstream of the promoter of *XLαs*. Although the promoters of *XLαs* and *GNAS-AS1* are located together within a large differentially methylated region (DMR), the female germline-specific imprint is established at the antisense promoter only.[87] The *A/B* promoter is likewise methylated in the female, but not in the male, germ cells.[88] Thus, the two gamete-specific imprint marks at the *GNAS* locus include the promoters of the *GNAS-AS1* and *A/B* transcripts. Accordingly, data from different genetically manipulated mouse models show that these noncoding transcripts are essential for the regulation of imprinted gene expression from *GNAS*.[86,89,90] Imprinted *A/B* transcription, that is, expression from only the nonmethylated maternal allele, is particularly important for the development of hormone resistance seen in patients with PHP1B (see later).

Unlike the promoters of the *NESP55*, *AS1*, *XLαs*, and *A/B* transcripts, the promoter of *Gsα* is not differentially methylated, and, accordingly, Gsα expression is biallelic in most tissues.[61,67,91] Biallelic Gsα expression has been specifically shown in human bone and white adipose tissue.[92] However, paternal Gsα expression is silenced in a small subset of tissues through as-yet-undefined mechanisms, so that the maternal allele is the predominant source of Gsα expression. These tissues include the renal proximal tubule, thyroid, pituitary, and gonads.[76,93-95] Although devoid of differential methylation, the Gsα promoter exhibits parent-of-origin specific histone modifications in those tissues where it is monoallelic. The active maternal Gsα promoter shows a greater ratio of tri- to dimethylated histone-3 Lys4 compared with the silenced paternal promoter in the proximal tubule, whereas the amount of methylated histones is similar in maternal and paternal Gsα promoters in liver, a tissue in which Gsα is biallelic.[96] As discussed later, the tissue-specific, paternal Gsα silencing has a key role in the development of PTH resistance in patients with PHP1A and PHP1B.

KEY POINTS

- The *GNAS* complex locus encodes the stimulatory G protein alpha-subunit (Gsα), which is critical for basal and receptor-activated cyclic adenosine monophosphate generation.
- Additional transcripts are also derived from *GNAS*, showing exclusively paternal or maternal expression (monoallelic) and differential methylation at their unique promoters. In contrast, Gsα expression is biallelic in most tissues, including bone and white adipose tissue; however, the paternal *Gsα* allele is silenced in a small set of tissues, including the renal proximal tubule, thyroid, brown adipocytes, gonads, and certain parts of the hypothalamus.
- Inactivating mutations affecting Gsα-coding *GNAS* exons cause multihormone resistance and Albright's hereditary osteodystrophy when located on the maternal allele, that is, pseudohypoparathyroidism type-Ia (PHP1A), whereas the same mutations cause some features of Albright's hereditary osteodystrophy (AHO) without hormone resistance when they occur on the paternal allele, that is, pseudopseudohypoparathyroidism (PPHP).
- AHO refers to a stellate of physical features including early-onset obesity, round face, short stature, brachydactyly, heterotopic ossification, and intellectual disability. Although obesity and intellectual disability appear to be present only when the Gsα mutation is maternal (i.e., part of PHP1A), the other AHO features are observed regardless of the parent of origin of the Gsα mutations (i.e., both PHP1A and PPHP).
- The underlying cause of this imprinted mode of inheritance in patients carrying Gsα mutations is the tissue-specific paternal silencing of the *Gsα* allele. In those tissues, the maternal inactivating mutation causes a dramatic loss of activity when combined with the already silenced paternal *Gsα* allele. The tissue-specific monoallelic expression of Gsα also explains the finding that, despite the ubiquitous expression of Gsα, hormone resistance is confined to a limited number of tissues.

CLINICALLY DISTINCT, GENETICALLY RELATED PSEUDOHYPOPARATHYROIDISM VARIANTS

Pseudopseudohypoparathyroidism

Physical abnormalities similar to those observed in patients with PHP1A but without evidence for an abnormal regulation of calcium and phosphate homeostasis were first reported in 1952.[97] Because of the lack of an abnormal regulation of mineral ion homeostasis, the name pseudopseudohypoparathyroidism (PPHP) was coined to describe this disorder.[97] Interestingly, patients with PPHP also carry *GNAS* mutations that lead to diminished Gsα function, and these mutations can be found in the same kindred as those with PHP1A. However, both disorders are never seen in the same sibling kinship, and a careful analysis of multiple families has revealed that the mode of inheritance of each disorder depends on the gender of the parent transmitting the Gsα mutations.[98] Thus, an inactivating Gsα mutation causes PHP1A (i.e., hormone resistance and AHO) when inherited maternally, whereas the same mutation results in PPHP (AHO only) if inherited paternally. Most AHO features, except obesity and intellectual disability, appear to develop regardless of the parent of origin, and it is therefore primarily hormone resistance that displays an imprinted mode of inheritance. Recent studies have furthermore revealed that most PPHP patients are considerably smaller at birth, particularly if their inactivating Gsα mutation is located in *GNAS* exons 2 to 13 of the paternal allele.[99,100]

The tissue-specific imprinting of Gsα expression can explain the parent-of-origin–specific inheritance of hormone resistance. In those tissues where Gsα expression is paternally silenced (i.e., Gsα is expressed exclusively or predominantly from the maternal allele), an inactivating mutation located on the paternal allele is not predicted to alter Gsα function, whereas the same mutation located on the maternal allele is predicted to abolish Gsα function completely (Fig. 57.6). The tissue-specific silencing of Gsα expression also explains why the target organ resistance involves only a small subset of tissues, despite the involvement of Gsα signaling in a multitude of physiological responses. Hormone resistance is observed in those tissues where Gsα

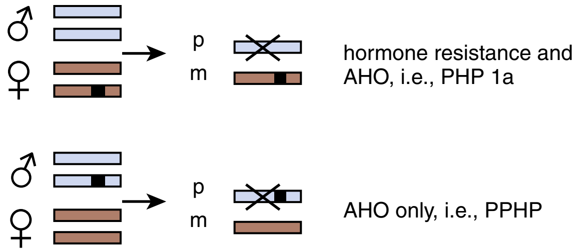

Fig. 57.6 The effect of paternal Gsα silencing in the development of hormone resistance. Gsα is biallelic in most tissues, and a heterozygous inactivating Gsα mutation therefore causes an approximately 50% reduction in Gsα activity/expression, regardless of the parent of origin of the mutation. However, in some tissues, such as the proximal tubule and thyroid, paternally inherited Gsα transcript is silenced (X). Thus, if a Gsα mutation (*black square*) is inherited from a female individual, this mutation nearly abolishes the expression or the activity of Gsα in those tissues, thus leading to hormone resistance (pseudohypoparathyroidism type-Ia; PHP1A). In contrast, upon paternal inheritance, the same mutation in Gsα does not lead to a significant change in the expression/activity, and thus the hormone responses are unimpaired. Paternal and maternal Gsα alleles are depicted by white or grey rectangles. *AHO*, Albright's hereditary osteodystrophy; *PPHP*, pseudopseudohypoparathyroidism.

is derived mainly from the maternal *GNAS* allele, such as the proximal renal tubule and the thyroid, while hormone responses are unimpaired in those tissues where Gsα is biallelic, such as the distal renal tubules and bone cells. The role of tissue-specific Gsα silencing in the development of PTH resistance has been demonstrated through the generation of mice heterozygous for maternal or paternal disruption of *GNAS*.[93] A recent study furthermore showed that the reduced paternal Gsα expression in the renal proximal tubule develops after the early postnatal period in mice,[101] thus providing a plausible explanation for the finding that the manifestation of PTH resistance occurs mostly after infancy in patients with PHP1A and PHP1B.[8,12,17]

The finding that most AHO features develop regardless of the parent transmitting a Gsα mutation has led to the hypothesis that the inheritance of AHO is caused by Gsα haploinsufficiency in various tissues, which appears to be true in certain settings. PTH-related protein–induced cAMP generation is critical for proper control of hypertrophic differentiation of growth plate chondrocytes,[102] and Gsα haploinsufficiency has been demonstrated in this tissue through the study of mice chimeric for wild-type cells and mutant cells heterozygous for disruption of *Gnas* exon 2.[103] Regardless of the parental origin of the *Gnas* exon 2 disruption, the mutant cells displayed premature hypertrophy compared with their wild-type neighbors, although the paternal disruption (i.e., loss of one *Gsα* allele combined with a complete loss of *XLαs*) resulted in significantly more premature hypertrophy than the maternal disruption (loss of one *Gsα* allele only). Thus, the brachydactyly and/or short stature observed in the context of AHO likely result from diminished Gsα signaling in growth-plate chondrocytes. Although these data correlate well with the notion that AHO develops after both maternal and paternal inheritance of a Gsα mutation, recent evidence suggests that individual AHO features can also be subject to imprinting. A careful analysis of multiple patients with PHP1A and PPHP revealed that obesity is primarily a feature of PHP1A patients, developing after maternal inheritance of the Gsα defect.[104] Considering that Gsα is biallelic in white adipose tissue,[92] it was proposed that Gsα may also be imprinted—predominantly maternal expression—in areas of the central nervous system that control satiety and body weight.[104] Recent reports have also demonstrated that cognitive impairment is encountered in PHP1A, but is not particularly prevalent in PPHP, thus indicating that tissue-specific Gsα imprinting may involve additional brain regions.[12,105] On the other hand, imprinted inheritance has not been reported regarding short stature, despite the finding that Gsα is maternally expressed in the pituitary[94,95] and the fact that PHP1A patients can display growth hormone-releasing hormone (GHRH) resistance that results in growth hormone (GH) deficiency.[33,106] Conversely, as outlined above, the small-for-gestational age phenotype is associated more strongly with *Gsα* mutations on the paternal allele than with *Gsα* mutations on the maternal allele.[100] A single study also showed that PPHP patients carrying mutations within exons 2 to 13 are born smaller than those carrying mutations within exon 1,[100] thus implicating both Gsα haploinsufficiency and the deficiency of a paternally expressed *GNAS* product, such as XLαs, in the pathogenesis. Future analyses of patients with PHP1A and PPHP will be helpful in determining the relative roles of genomic imprinting and haploinsufficiency in the development of individual AHO features.

Progressive Osseous Heteroplasia

A disorder termed progressive osseous heteroplasia (POH) has been described in patients with severe extraskeletal ossifications that involve deep connective tissue and skeletal muscle[107] (Fig. 57.7). In POH, the ectopic bone is primarily intramembranous, as opposed to a similar disease of heterotopic bone formation, termed fibrodysplasia ossificans progressiva, in which extraskeletal bone formation occurs via endochondral mechanisms and is accompanied by congenital skeletal malformations.[108] Few patients with POH demonstrate AHO features, and, consistent with the occasional coexistence of these two sets of clinical defects, heterozygous inactivating Gsα mutations have been identified as a cause of POH.[109,110] Several of the identified mutations are identical to those identified in PHP1A/PPHP kindreds.[109,110] Gsα activity and downstream signaling has been implicated in the control of osteogenic differentiation. Thus, patients who are mosaic for heterozygous *GNAS* mutations that result in constitutive Gsα activity develop fibrous dysplasia of bone characterized by irregular woven bone disrupted by fibrous tissue.[111] Moreover, in human mesenchymal stem cells, reduction of Gsα protein levels has been shown to cause osteogenic differentiation, while inhibiting the formation of adipocytes.[112,113] In addition, Runx2, a key regulator of osteoblast-specific gene expression, appears to suppress Gsα expression.[114] Thus, osteoprogenitor formation and the early stages of osteoblastic differentiation require reduced levels of cAMP signaling, consistent with the association of inactivating Gsα mutations with the severe ectopic bone formation observed in POH.

Because of the presence of *GNAS* mutations in both AHO and POH, it appears that additional factors, such as genetic background, epigenetic events, second hits, or environmental factors may determine the penetrance and severity of the ectopic ossifications in these patients who show approximately 50% loss of Gsα activity. Nevertheless, clinical and genetic data demonstrate several important differences between patients with AHO and those with POH. First, the ectopic bone in AHO is limited to subcutaneous tissue. In addition, in nearly all patients with POH, the severe ectopic bone formation is isolated (i.e., other typical AHO features are not manifest).[110,115] Moreover, mutations leading to isolated POH occurred either *de novo* on the paternal *GNAS* allele or are inherited from male obligate gene carriers only (i.e., the inheritance pattern is exclusively paternal).[110] In fact, in one large kindred, paternal inheritance of a *GNAS* mutation caused POH, while maternal inheritance of the same mutation caused typical AHO findings (without severe heterotopic ossification).[110] These findings indicate that the disease mechanism underlying POH is significantly different from that underlying AHO, and that deficiency of a *GNAS* product with exclusive paternal expression, such as XLαs, contributes to the molecular pathogenesis of POH. In addition, a study analyzing 12 patients with POH revealed that the lesions follow a predominantly dermomyotomal distribution that often shows a lateralization bias.[116] Based on these findings, it was hypothesized that the pathogenesis involves progenitor cells of somitic origin, which may undergo loss of heterozygosity at the *GNAS* locus and thereby cause severe Gsα deficiency.[116] Accordingly, complete ablation of Gsα in mouse mesenchymal tissues leads to POH-like skeletal findings.[117] In the ectopic bone lesions of POH patients, Hedgehog signaling is activated, which appears to be necessary and sufficient for the formation of Gsα-related ectopic bone in mouse models.[118]

Disorders of Concurrent Gsα Inactivity and Hyperactivity

Complex phenotypes have been described in several patients carrying *GNAS* mutations in whom the phenotype variably included PHP-like features combined with clinical findings that reflect hyperactivity of Gsα signaling and/or impaired Gsα activity in atypical tissues.

Testotoxicosis and Pseudohypoparathyroidism. A missense mutation in exon 13 (A366S) was identified in two unrelated boys who presented with PHP1A and precocious puberty.[119,120] This mutant Gsα

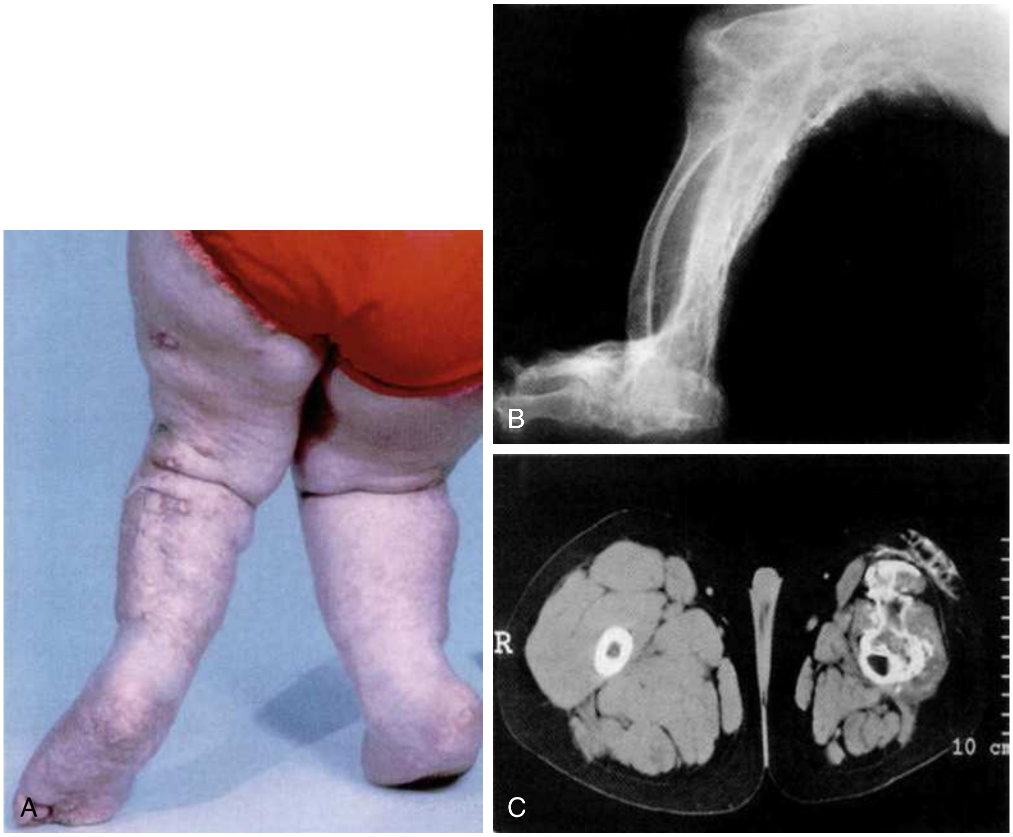

Fig. 57.7 Clinical and radiographic appearance of progressive osseous heteroplasia (POH). **A,** Posterior view of the legs and feet of a 5-year-old girl with POH, showing severe maculopapular lesions caused by extensive dermal and subcutaneous ossification. **B,** A lateral radiogram of the right leg of an 11-year-old girl with POH demonstrating severe heterotopic ossification of the soft tissues. **C,** Computed tomographic image of the thighs of a 10-year-old boy with POH, showing atrophied soft tissues in the left leg and extensive ossification of the skin, subcutaneous fat, and quadriceps muscles. (Modified from Shore EM, Ahn J, Jan de Beur S, et al. Paternally inherited inactivating mutations of the *GNAS1* gene in progressive osseous heteroplasia. *N Engl J Med*. 2002;346:99–106.)

protein is temperature-sensitive and thus rapidly degraded at normal body temperature. The amino acid substitution, however, renders the protein constitutively active, resulting in elevated cAMP signaling in the cooler temperature of the testis. More recently, two unrelated male patients have been reported to have another Gsα missense mutant (F376V) associated with severe early-onset precocious puberty combined with evidence of hormonal resistance.[121] Both patients presented with asymptomatic infantile-onset hyponatremia because of nephrogenic syndrome of inappropriate antidiuresis and also developed skeletal and growth plate abnormalities. As revealed by *in vitro* functional studies, the mutant protein exhibits enhanced receptor-dependent basal cAMP for several G protein-coupled receptors tested, including the lutropin/choriogonadotropin receptor, the PTHR1, and the vasopressin receptor type-2, while showing blunted ligand-induced activation. Thus, the observed clinical findings reflect both a loss and a gain of Gsα activity in a wide variety of tissues.

Other Complex Phenotypes of Altered Gsα Activity. Another mutant Gsα protein has been described in a unique case of familial PHP1A and transient neonatal diarrhea.[122] The mutation, which entails a repeated AVDT sequence at residues 366 to 369, generates an unstable but constitutively active Gsα mutant because of enhanced GDP-GTP exchange and reduced GTPase activity. Although hormone resistance results from the instability of the Gsα-AVDT mutant, the diarrhea is attributed to increased plasma membrane localization of the mutant protein in the small intestine epithelium. Another pediatric case has been described in which a *de novo* missense mutation (R231C) on the paternal allele was found together with a maternally inherited combination of three C-to-T substitutions resulting in aberrant *GNAS* splicing.[123] The patient with these compound heterozygous mutations had morbid obesity, TSH and PTH resistance, and a prothrombotic state owing to marked Gsα hypofunction in platelets.

KEY POINTS

- Heterozygous Gsα-coding mutations are rarely associated with severe ectopic bone formation, termed progressive osseous heteroplasia (POH). In those cases, the heterotopic bone invades the skeletal muscle and deep connective tissue, thus causing severe restriction of motion.
  - POH is mostly inherited paternally or found *de novo* in association with the mutant paternal *GNAS* allele.
    - The pathogenesis of POH involves progenitor cells of somitic origin, which may undergo loss of heterozygosity at the GNAS locus and thereby have severe Gsα deficiency.

PSEUDOHYPOPARATHYROIDISM TYPE-Ib

Another form of PHP was described by Peterman and Garvey[124], by Reynolds et al[124] and by Farfel et al.[43] Now known as PHP type-Ib (PHP1B), this PHP form is characterized by the presence of PTH resistant hypocalcemia and hyperphosphatemia, but without any evidence of AHO. In addition to increased serum PTH, patients with PHP1B can demonstrate elevated serum alkaline phosphatase activity, which suggests normal PTH-dependent bone turnover.[126] In fact, hyperparathyroid bone disease can be observed in association with PHP1B, especially in patients with sporadic PHP1B or in the index cases of the autosomal dominant form of PHP1B (AD-PHP1B). This occurs less frequently, however, in PHP1A, as this variant is associated with AHO features and is therefore diagnosed earlier in life. The intact PTH response in the bone is consistent with the lack of Gsα imprinting in bone[92] and led to the introduction of the term "pseudohypo-hyperpa rathyroidism."[127-129]

The hormone resistance observed in PHP1B patients develops only after maternal inheritance of the genetic defect[130] (i.e., the mode of inheritance is identical to the hormone resistance in PHP1A). PTH resistance and related changes in calcium and phosphate homeostasis are the major laboratory findings in PHP1B, but some of these patients also display mild hypothyroidism with slightly elevated TSH levels,[131-134] as well as some elevation in calcitonin level.[131] Hypothyroidism, as in patients with PHP1A, likely results from mild TSH resistance and is consistent with the predominantly maternal Gsα expression in the thyroid.[95,133] Nevertheless, evidence for resistance to other hormones, such as gonadotropins, whose actions also involve tissues in which paternal Gsα expression can be silenced, has not been reported for PHP1B patients. A study assessed GH response to GHRH plus arginine stimulation in PHP1B, revealing a normal response in 9 of 10 patients.[134] On the other hand, in addition to PTH and mild TSH resistance, hypouricemia because of increased fractional excretion of uric acid has been reported in the affected individuals of two unrelated PHP1B kindreds.[135,136] This finding implicates impaired PTH actions in the development of reduced uric acid levels in these patients, an interpretation that is consistent with two previous reports describing hyperuricemia in association with hyperparathyroidism.[137,138] However, hypouricemia resolved in one of the PHP1B kindreds following treatment with calcium and calcitriol.[136]

Patients with PHP1B display normal Gsα bioactivity/levels in easily accessible tissues.[43] Accordingly, coding Gsα mutations are ruled out in these patients. In one family, however, a mutation located in exon 13 (in-frame deletion of Ile^{382}, del382Ile) was reported, leading to the uncoupling of Gsα from the PTHR1 but not other receptors, including TSH receptor, luteinizing hormone receptor, and β-adrenergic receptor,[139] that were expressed in LLCPK cells, which are of renal origin and express endogenous Gsα. These findings suggested an isolated PTH resistance as seen in PHP1B, leading to the conclusion that the del382Ile mutation in Gsα represents a rare cause of PHP1B. However, this conclusion has been questioned, as the use of transfected mouse embryonic fibroblasts null for endogenous Gsα showed that del382Ile leads to uncoupling from not only PTHR1 but also the β-adrenergic receptor.[21] Because of a lack of Gsα mutations, and because Gsα activity/levels in easily accessible tissues are normal in PHP1B patients, inactivating mutations that affect the gene encoding PTHR1 was considered in the past.[140] However, several different studies have excluded such mutations as the cause of this disease.[141-144] Instead, homozygous or compound heterozygous inactivating mutations of *PTHR1* have been revealed as the cause of Blomstrand chondrodysplasia, an embryonic lethal disorder involving severe skeletal abnormalities.[145] Homozygous *PTHR1* mutations were furthermore identified in patients with Eiken syndrome, an autosomal recessive skeletal dysplasia,[146] and heterozyous inactivating *PTHR1* mutations were observed in several families with an autosomal dominant form of delayed tooth eruption,[146-149] that is, disorders without evidence for hypocalcemia and hyperphosphatemia because of impaired actions of PTH.

Based on genome-wide linkage analysis, the genetic defect underlying PHP1B was mapped to a region of chromosome 20q13.3 that comprises the *GNAS* locus,[130] but the critical interval excluded all the coding *GNAS* exons, including those that encode Gsα.[27,132] On the other hand, patients with PHP1B display epigenetic abnormalities within the *GNAS* locus.[132,150] The most consistent epigenetic defect is a loss of imprinting at exon A/B (also termed exon 1A), which is primarily found as an isolated defect in most familial PHP1B cases.[132,150] In addition, many sporadic, and some familial, PHP1B cases show additional loss of imprinting at the DMR comprising the XLαs and antisense promoters and gain of imprinting at the DMR comprising the NESP55 exon.[150,151] These abnormalities are associated with biallelic expression of A/B, XLαs, and antisense transcripts and the silencing of NESP55 transcript. Together with the genetic linkage data, these imprinting defects suggest that the mutation causing PHP1B disrupts a regulatory element that controls *GNAS* imprinting. However, evidence for incomplete penetrance regarding the *GNAS* imprinting defects has been reported in one kindred, in whom some individuals lacked loss of imprinting and were healthy despite maternally inheriting the disease-associated haplotype.[152] Thus, methylation abnormalities of *GNAS* are required for the development of PHP1B.

Autosomal Dominant PHP1B

In multiple familial PHP1B cases with isolated exon A/B loss of imprinting, a unique 3-kb microdeletion at the centromeric neighboring *STX16* locus has been identified[153] (Fig. 57.8). The deleted region comprises *STX16* exons 4 to 6 and is flanked by two direct repeats, which may underlie the mechanism whereby this deletion occurs. This is consistent with the presence of the same microdeletion in many unrelated families with different ethnic and racial origin.[12] In a single kindred, a different microdeletion within *STX16* has been reported, removing exons 2 through 4 and overlapping with the 3-kb microdeletion by approximately 1.3 kb.[17] Recently, larger maternally inherited deletions comprising either *STX16* exons 2 to 8 or all *STX16* and *NPEPL1* exons have been discovered in single families with this disorder.[154–156] Thus, the disruption of *STX16* appears to be a frequent genetic defect in cases with isolated loss of exon A/B imprinting. The parental origin of these *STX16* deletions correlates well with the mode of inheritance of PHP1B. It is maternally inherited in affected individuals and paternally inherited in unaffected carriers. This gene encodes syntaxin-16, a member of the SNARE family of proteins. However, *STX16* does not appear to be imprinted,[17,153] and it is therefore unlikely that the loss of one *STX16* copy leads to PHP1B. Instead, because the maternal inheritance is associated with loss of exon A/B imprinting on the same allele, these deletions are presumed to disrupt a cis-acting element controlling the establishment or maintenance of exon A/B imprinting. Other than genetic evidence, however, no currently available data corroborate this prediction. A mouse model carrying a deletion equivalent to the 3-kb *STX16* deletion in humans has been generated, but neither maternal nor paternal inheritance of this genetic alteration causes PTH resistance or any alterations in *GNAS* imprinting[157]; animals with the homozygous *Stx16* deletion are also healthy. It thus appears plausible that the imprinting control element of *GNAS* located within *STX16* in the human is not precisely at the same location in the mouse. Nonetheless, the absence of a phenotype in the *Stx16* deletion mice argues against a model in which syntaxin-16, the product of this gene, is required in the oocyte for proper exon A/B imprinting.

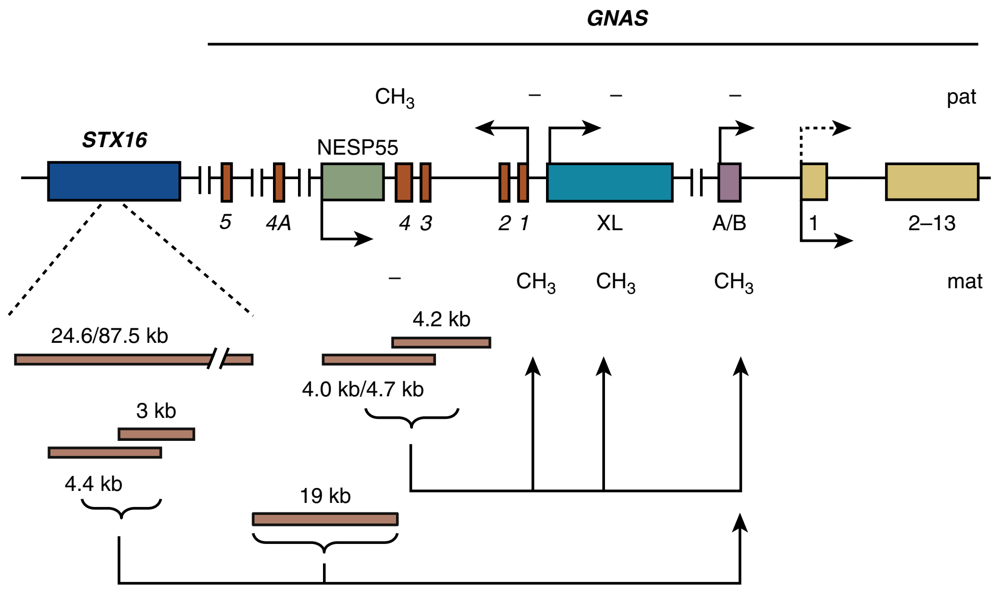

Fig. 57.8 Mutations identified in autosomal dominant pseudohypoparathyroidism type-Ib (AD-PHP1B) patients and their effects on *GNAS* imprinting. Most frequent mutation is a 3-kb deletion within *STX16*, a gene located more than 200 kb upstream of *GNAS*. This deletion and other overlapping deletions in the same gene are predicted to disrupt a cis-acting control element of *GNAS* that is required for the imprint mark located at exon A/B. The same prediction is also true for a 19-kb deletion of NESP55 and upstream genomic regions, which was identified in affected individuals of an AD-PHP1B kindred with isolated loss of A/B methylation. In addition, large duplications or genomic rearrangements involving the *GNAS* locus, such as a large inversion with a breakpoint in the intron between XLαs and A/B, have also been described as a cause of certain PHP1B cases that show loss of methylation at exon A/B alone. Deletions of the NESP55 DMR including exons 3 and 4 of the antisense transcript and a more recently identified deletion that only includes antisense transcript exons 3 and 4 have been identified in some AD-PHP1B kindreds. These reveal a cis-acting element controlling imprinting of the entire maternal *GNAS* allele. Boxes and connecting lines indicate exons and introns, respectively. *STX16* exons and *GNAS* exons 2–13 are shown as single rectangles for simplicity. Paternal (pat) and maternal (mat) methylation (CH_3) and parental origin of transcription (*arrows*) are indicated. Tissue-specific silencing of paternal Gsα transcription is depicted by a dotted arrow. The identified deletions are shown by brown horizontal bars.

In two unrelated familial cases of PHP1B in whom the affected individuals carried broad *GNAS* imprinting defects, maternally inherited deletions of the entire NESP55 DMR, including exons 3 and 4 of the antisense transcript, have been identified (Fig. 57.8).[85] The deletions are 4 kb and 4.7 kb in size and have breakpoints located in similar locations. The unaffected carriers in these families display an apparent loss of *NESP55* methylation because of the loss of this region from the normally methylated paternal allele, but do not show other imprinting *GNAS* defects. The affected individuals show a loss of imprinting in the entire maternal allele. The presence of similarly large deletions at the *NESP55* DMR has been excluded in a number of sporadic PHP1B cases.[85,151] However, a different 4.2-kb deletion has been identified in the affected individuals of a different PHP1B kindred who displayed broad *GNAS* imprinting defects (Fig. 57.8).[158] The latter deletion also includes antisense exons 3 and 4 but spares exon NESP55, overlapping with the previously identified two deletions by approximately 1.5 kb.[158] A small deletion adjacent to, but not affecting, NESP55 was also found in a kindred with two affected siblings who showed complete paternalization of the *GNAS* methylation pattern.[159] However, the clinically and epigenetically unaffected mother of the affected siblings had inherited the variant from her own mother, thus raising concerns that an as-yet identified mutation, rather than the identified deletion, is responsible for the disease in the siblings.[159]

A study revealed a 19-kb genomic deletion removing exon NESP55 and a large portion of the intron between NESP55 and antisense exon 4, but not including this exon, in a kindred with AD-PHP1B with isolated loss of A/B methylation.[160] Another 9-kb deletion removing NESP55 and the upstream genomic region has also been identified, which is also associated with isolated A/B methylation loss.[156] In addition, a 1.9-Mb genomic inversion has been discovered in a PHP1B kindred with isolated loss of *A/B* methylation, whose centromeric breakpoint disrupts the *GNAS* gene in its large intron separating the first exon of XLαs and A/B.[161] Furthermore, a family has been described in which a duplication within the *GNAS* locus spanning NESP55 and the first exons of XLαs led to loss-of-methylation at exon A/B alone, with methylation alterations in the other DMRs reflecting the duplication event.[162] Similarly, a duplication-triplication-duplication rearrangement involving approximately 95 kb of the *GNAS* locus, including all DMRs but not *STX16* or the Gsα coding region, has been identified in a PHP1B kindred, and this genetic alteration was associated with a complete loss of *A/B* methylation that could not be ascribed to the copy number changes.[163] Because all these patients lacked broad *GNAS* methylation abnormalities, the identified genetic alterations suggest the existence of another control element of specific to A/B methylation. The study of a mouse model in which Nesp55 transcription was prematurely truncated revealed loss of imprinting at exon 1A (the equivalent of human exon A/B) and, less consistently, the antisense promoter and exon XL.[164] Taken together with the genetic findings in PHP1B patients, it appears that the establishment of methylation imprints on the maternal *GNAS* allele is essential for allowing expression of Gsα in the proximal renal tubule and other tissues, including the thyroid, in which this *GNAS* product is derived only from the maternal allele. Furthermore, the evidence that exon *A/B* methylation requires transcription from the *NESP55* promoter[164] raises the possibility that even small deletions or point mutations can prevent the generation of *NESP55* pre-mRNA, thus leading to PHP1B.

Sporadic Pseudohypoparathyroidism Type-1B

Most cases of PHP1B are sporadic, (i.e., there are no affected family members). These cases all show broad *GNAS* methylation defects. Accordingly, approximately 10% of sporadic PHP1B cases have paternal uniparental isodisomy involving all of chromosome 20 or the parts that comprise the *GNAS* locus[131,165] Few patients were described to have *de novo* or maternally inherited genetic alterations affecting this gene. A large deletion has been identified in one case, comprising two adjacent deletions of approximately 38 kb and 1.4 kb and removing the region between the antisense exons 3 and 5, including exon NESP55; the deletion was found to be maternally inherited.[166] Additionally, a *de novo* large duplication (~320 kb) has been discovered, including the entire *GNAS* locus, as well as several neighboring genes, in a patient who displayed broad alterations in *GNAS* methylation.[162]

However, the maternal allele is frequently shared between affected and unaffected siblings, suggesting that these cases may carry small *de novo* mutations in this region. However, in some families the affected female passed either allele #1 or allele #2 to their children, who are all unaffected by PHP1B and show no methylation abnormalities at the *GNAS* locus.[167,168] It is therefore possible that some of the sporadic PHP1B cases carry homozygous or compound heterozygous mutations in an entirely different genomic location, resulting in a putative autosomal recessive mode of inheritance.[167] Consistent with this conclusion, few patients affected by imprinting disorders without obvious PTH resistance show *GNAS* methylation changes.[169,170] Moreover, methylation changes in some other imprinted genomic loci have been revealed in a study of sporadic PHP1B cases.[171] It has also been suggested that the broad *GNAS* imprinting defects observed in sporadic PHP1B patients result from stochastic defects in the regulation of imprinting.[172] Consistent with this hypothesis, the broad *GNAS* methylation defects are partial in some sporadic PHP1B cases, suggesting that those cases are mosaic for aberrant and normal cells. Investigating individual patients with incomplete methylation abnormalities, a recent study found no significant difference between organs and tissues in terms of the extent of the partial *GNAS* methylation defects, suggesting that those are acquired during early postzygotic development.[173]

Despite having distinct epigenetic abnormalities at the *GNAS* locus (i.e., isolated A/B loss of imprinting vs. broad imprinting defects that involve exon A/B and at least one other *GNAS* DMR), PHP1B patients seem to have similar clinical findings with respect to serum calcium, phosphate, and PTH levels.[151] Analysis of 20 families in which the affected individuals show an isolated loss of A/B imprinting revealed that a significant portion of such familial cases are asymptomatic at the time of diagnosis. In some of these cases, the diagnosis was made only based on elevated serum PTH. Comparison of male and female patients among sporadic PHP1B cases who exhibit *GNAS* imprinting defects at two or more *GNAS* DMRs also reveals that female patients have significantly higher serum PTH levels than male patients, suggesting that hormone resistance is more severe in females.[151]

Albright's Hereditary Osteodystrophy Features Associated With Cases With *GNAS* Methylation Defects. By definition, PHP1B patients do not show AHO features. However, some reports identified patients who carry genetic and epigenetic defects associated with PHP1B yet present with mild AHO features, particularly the shortness of metacarpal bones or Madelung-like deformities.[174,175]. This may suggest that Gsα imprinting occurs in more tissues than currently recognized, although there are alternative explanations. Considering that individual AHO features can be observed in other disorders, the presence of AHO features may be unrelated to the molecular genetic defects underlying PHP1B in these cases. In one case, the mother of two affected siblings with short metacarpals and loss of *A/B* methylation also exhibited short metacarpals, despite lacking any *GNAS* epigenetic abnormalities,[174] suggesting that the finding of short metacarpals is unrelated to the epigenetic defect in that family. In addition, the observed coexistence of *GNAS* imprinting defects and AHO can result from a large genomic deletion comprising at least the promoter of *Gsα* and one or more differentially methylated regions. In fact, such a large deletion leading to misdiagnosis of PHP1B has been discovered in a case with apparent loss of *A/B* methylation and AHO features.[176]

KEY POINTS

- Patients with pseudohypoparathyroidism type Ib (PHP1B) show renal parathyroid hormone resistance, often with mild thyroid-stimulating hormone resistance, typically in the absence of Albright's hereditary osteodystrophy. However, some PHP1B patients can have physical features that resemble Albright's hereditary osteodystrophy.
- PHP1B is often sporadic but can also be inherited in a maternal-specific autosomal dominant manner (AD-PHP1B).
- Alterations of the *GNAS* methylation pattern are associated with PHP1B. All PHP1B cases display a loss of methylation at *GNAS* exon A/B (also known as 1A). Most sporadic PHP1B (and a few AD-PHP1B) cases furthermore show methylation abnormalities at the other differentially methylated regions of *GNAS*.
- Various deletions, duplications, or rearrangements within or near the *GNAS* locus have been identified as the cause of the methylation alterations in PHP1B.
- The most frequent genetic cause of AD-PHP1B is a 3-kb microdeletion located within the neighboring *STX16* gene located ~200 kb centromeric of *GNAS*.
- The loss of *GNAS A/B* methylation, which is the most consistent epigenetic alteration, is predicted to silence, in cis, the expression of Gsα from the maternal allele. This leads to a dramatically reduced Gsα level in those tissues in which the paternal Gsα allele is already silenced via normal genomic mechanisms.

PSEUDOHYPOPARATHYROIDISM TYPE-II

Dissociation regarding the impairment of PTH-induced nephrogenous cAMP formation and phosphaturia (i.e., PHP2) appears to be the least common form of PHP. Although typically sporadic, a case with familial form of PHP2 type has been reported,[177] and several reports describe evidence for a self-limited form of this disease in newborns, which could indicate that it is transient in nature.[178-180] The molecular defect and pathophysiological mechanisms underlying this PHP variant remain to be discovered. Because the defect underlying PHP2 is associated with normal cAMP generation in response to exogenous PTH, it was postulated that it is caused by molecular defects that involve factors downstream of cAMP generation, such as protein kinase A (PKA).[181] In fact, mutations in the regulatory subunit of PKA have been identified in some patients who show, in association with characteristic skeletal abnormalities, biochemical defects similar to those seen in PHP2 (see later). Alternatively, the PTH signaling pathways that use other G proteins, such as Gq or G_{11}, may be defective in patients with PHP2. The signaling mediated by Gq/G_{11} pathway involves activation of phospholipase C, which in turn leads to the formation of second messengers inositol 1,4,5 tris-phosphate (IP3) and diacylglycerol. This signaling pathway, which results in the stimulation of protein kinase C (PKC) and an increase in intracellular calcium ions, was shown to be important in sustaining the phosphaturic actions on PTH, as recently shown for mice expressing a PTHR1 mutant that fails to activate IP3/PKC signaling.[182] Serum calcium levels, which may affect the efficient utilization of intracellular calcium signaling pathways, appear to be important for restoring PTH responsiveness in PHP2, as shown in some patients who normalized their phosphaturic response to PTH following normalization of serum calcium.[183] It is also possible that the sodium-phosphate transporters in the proximal renal tubule are nonresponsive to PTH, thereby resulting in a defective phosphaturic, but not cAMP, response to exogenous PTH. Such a defect, however, should preserve the action of PTH on 25(OH)D-1-α-hydroxylase and lead to normal serum 1,25$(OH)_2$D, unless it is combined with vitamin D deficiency. Hypocalcemia as a result of vitamin D deficiency has also been associated with PTH resistance that entailed the phosphaturic effect of this hormone without altering its potential to raise urinary cAMP,[184] suggesting that some PHP2 cases may in fact reflect vitamin D deficiency.[185,186]

ACRODYSOSTOSIS WITH HORMONAL RESISTANCE

A recent report described three patients who had resistance to PTH and some other hormones but showed unimpaired urinary cAMP excretion in response to exogenously administered recombinant PTH.[187] Consistent with resistance to the actions of PTH downstream of cAMP/PKA, PTH-induced urinary phosphate excretion was lost, and PTH-induced inhibition of urinary fractional calcium excretion was impaired. These unrelated patients, who could thus be classified as having a variant of PHP2 based on their renal PTH responsiveness, also displayed acrodysostosis, a skeletal dysplasia that resembles, but is more severe than, the skeletal defects observed in AHO. Acrodysostosis, also known as Maroteaux–Malamut syndrome, include severe brachydactyly, peripheral dysostosis, and nasal hypoplasia.[188,189] Analysis of DNA from these patients revealed a recurrent heterozygous nonsense mutation of the gene encoding cAMP-dependent protein kinase type I-alpha regulatory subunit (PRKAR1A; p.Arg368X). This mutation leads to a mutant PRKAR1A protein missing the last 14 C-terminal amino acids. Accordingly, cAMP cannot induce dissociation of this mutant regulatory subunit from the catalytic subunit, thereby keeping PKA in its inactive form. Several other patients with acrodysostosis have been described in more recent studies in which additional PRKAR1A mutations have been documented.[190,191] Note that the distal tubular actions of PTH appear to be impaired in patients with acrodysostosis, unlike in patients with PHP1A and PHP1B, who appear to show normal biallelic expression of Gsα in the distal renal tubule. Nevertheless, the similarity between this disorder and PHP1A with respect to the repertoire of hormone resistance is quite striking and highlights the critical nature of the cAMP signaling pathway in the actions of these hormones (Fig. 57.9).[192]

Acrodysostosis with hormone resistance

Fig. 57.9 Mutated components of the cyclic adenosine monophosphate (cAMP) signaling pathway in pseudohypoparathyroidism and acrodysostosis. Gsα is essential for stimulation of cAMP generation, which binds to the regulatory subunits of protein kinase A (*PKA*) and thereby renders the catalytic subunits active. cAMP-specific phosphodiesterases 4D (*PDE4D*) and 3A (*PDE3A*) hydrolyze cAMP and thereby control its intracellular levels. Heterozygous mutations of *PTHLH*, encoding parathyroid hormone–related peptide (PTHrP), are responsible for brachydactyly and short stature, while homozygous or compound heterozygous mutations in the PTH/PTHrP receptor gene (*PTHR1*) are the cause of Blomstrand's lethal chondrodysplasia. Homozygous *PTHR1* deletions are associated with Eiken syndrome, and several heterozygous *PTHR1* mutations cause autosomal dominant delayed tooth eruption. Maternally inherited heterozygous inactivating mutations in Gsα-coding *GNAS* exons or deletions disrupting the imprinting of *GNAS* lead to pseudohypoparathyroidism type-Ia or pseudohypoparathyroidism type-Ib, respectively, resulting in resistance to parathyroid hormone, and frequently other hormones. Heterozygous mutations in *PRKAR1A* or *PDE4D* can also lead to resistance toward multiple hormones and are the cause of acrodysostosis. *PDE3A* mutations are responsible for severe hypertension and brachydactyly with short stature. AHO, Albright's hereditary osteodystrophy; ATP, adenosine triphosphate. (Modified from Silve C, Jüppner H. Genetic disorders caused by mutations in the PTH/PTHrP receptor and downstream effector molecules. In: Bilezikian JP, ed. *The Parathyroids*. 2014 Academic Press, San Diego.)

Defects in the gene encoding another protein within the cAMP signaling pathway, cAMP phosphodiesterase type 4D (PDE4D), have also been identified upon exome sequencing of DNA from some patients with acrodysostosis.[23,24,191,193,194] The heterozygous missense mutations in PDE4D are associated with acrodysostosis, but most patients lack endocrine abnormalities. The underlying biochemical mechanisms have yet to be elucidated. It is predicted, however, that the PDE4D mutations are gain-of-function, given that PDE4D limits the intracellular level of cAMP.[195] Interestingly, another subtype of cAMP phosphodiesterase is affected in another disorder: patients with heterozygous PDE3A mutations show severe hypertension and brachydactyly type-E with short stature.[25,196]

TREATMENT

The primary goal of treatment entails correction of abnormal serum biochemistries that result from PTH and, in some cases, other hormone resistance, such as TSH resistance leading to hypothyroidism, which can be treated by thyroid hormone replacement. GH deficiency can also be treated with recombinant human GH (rhGH) and is found to be efficacious in prepubertal patients with PHP1A.[12] PPHP patients who carry *de novo* mutations in the paternal *GNAS* allele are often diagnosed late in life (often when the children of female patients with PPHP are diagnosed with PHP1A), making it difficult to assess GH deficiency, and thus the benefits of rhGH treatment in PPHP patients. Clinical management of hypocalcemia in patients with PHP1A and PHP1B is less difficult than in patients with hypoparathyroidism because the distal tubular actions of PTH in PHP1 patients are not impaired, providing sufficient calcium reabsorption from the glomerular filtrate. The treatment involves oral calcium supplements and activated vitamin D analogs, such as $1,25(OH)_2D$ (calcitriol). Note that the active form of vitamin D is required, because of the lowered capacity of the proximal tubule to convert 25(OH)D into the biologically active $1,25(OH)_2D$. In addition, treatment of patients with PTH resistance should aim at keeping the serum PTH level within or close to the normal range, rather than simply avoiding symptomatic hypocalcemia, as persistent elevation of serum PTH will increase bone resorption and may eventually lead to hyperparathyroid bone disease.[197] Because of intact PTH actions in the distal tubule, urinary calcium levels are usually low, and affected individuals do not have a significant risk of developing kidney stones and nephrocalcinosis. In fact, during the course of the treatment, elevation of urinary calcium typically does not occur. Nevertheless, blood chemistries and urinary calcium excretion in patients undergoing treatment should be monitored annually, but more frequently during pubertal development and once skeletal growth is completed, as the requirements for treatment with calcium and $1,25(OH)_2D$ may need to be reduced.

SUMMARY

PHP refers to a group of disorders characterized by PTH resistance associated with hypocalcemia, hyperphosphatemia, and elevated serum PTH. Proximal tubular resistance to PTH is the most prominent hormonal defect, but, depending on the underlying genetic defect, resistance to other hormones is also observed. PTH and these other hormones all exert their actions via receptors that couple to Gsα. The primary genetic causes of PHP1 and related disorders are mutations that affect the complex *GNAS* locus, the gene encoding Gsα. These mutations result in decreased expression/activity of Gsα but also affect some of the other gene products derived from *GNAS*. The nature and the parental origin of the *GNAS* mutation is an important determinant of the clinical manifestations. Mutations that affect coding Gsα exons lead to broader clinical abnormalities than mutations that disrupt parent-specific *GNAS* methylation. Because of the tissue-specific silencing of paternal Gsα expression, hormone resistance develops only after maternal inheritance. AHO typically occurs after both maternal and paternal inheritance of coding Gsα mutations, although the repertoire of some AHO features also follows an imprinted mode of inheritance. PPHP is used to describe those patients with AHO who lack hormone resistance. AHO features vary markedly. An extreme manifestation of AHO is POH, which appears to develop when Gsα mutations are present on the paternal allele. PHP2 is rare, and the molecular determinants of at least few variants with concurrent skeletal dysplasia, that is, acrodysostosis, involve the regulatory subunit of PKA and cAMP phosphodiesterases.

Future Directions, 1004

Vitamin D is a key regulator of mineral homeostasis[1,2] and bone development,[3] and perturbation of the vitamin D endocrine system leads to impaired calcium regulation that can lead to rickets and/or osteomalacia. In contrast, failure to destroy the active form of vitamin D leads to overexpression of the vitamin D–regulated genes and hypercalcemia. To gain a complete perspective of the clinical manifestations of genetic anomalies involving vitamin D endocrine function, this chapter will first present a short overview of the salient aspects of the vitamin D metabolic pathway. These notions will lay the groundwork for the discussion of the clinical, pathophysiological, and molecular aspects of hereditary diseases involving the vitamin D endocrine system.

OVERVIEW OF VITAMIN D METABOLISM

Following exposure to sunlight, both plants and animals are able to synthesize vitamin D. Vitamin D_2 is generated in yeast and plants; vitamin D_3 is produced in fish and mammals. The slight differences in the chemical structure of the two compounds do not affect function or metabolism. The generic term of vitamin D (without subscript) will be used hereafter.

In humans, a sizeable proportion of vitamin D requirements can be produced endogenously in the skin upon exposure to ultraviolet light (sunlight). It has been shown, however, that at latitudes where vitamin D synthesis is reduced or absent during winter months, there is a seasonal variation in the photosynthesis of vitamin D.[4] People who receive an ample supply of sunlight during the rest of the year are not at risk of developing vitamin D deficiency, because excess cutaneously produced vitamin D is stored in fat and muscle and released at times of need.[5] Dietary sources such as fish, plants, and grains can help meet vitamin D requirements. In the absence of any exposure to sunlight, however, such as in elderly people, a daily multivitamin that contains 800 IU of vitamin D is indicated.[6]

Ultraviolet B photons (270–290 nm) penetrate the epidermis and photolize 7-dehydrocholesterol into previtamin D, which rapidly becomes a more thermodynamically stable molecule, vitamin D.[7] Vitamin D then exits the keratinocyte cells and enters the dermal capillary bed, where it becomes bound to vitamin D–binding protein (DBP). Once associated with DBP in the circulation, vitamin D is transported to the liver, where the cytochrome P450 25-hydroxylase enzyme CYP2R1 adds a hydroxyl group on carbon 25 to produce 25-hydroxyvitamin D [25(OH)D]. Although several cytochrome P450 molecules can mediate the 25-hydroxylation of vitamin D to 25(OH)D *in vitro*,[8-11] findings from patients with vitamin D hydroxylation–deficient rickets, type 1B (VDDR1B), discussed later, confirm that CYP2R1 is the principal human vitamin D 25-hydroxylase.[12-15]

The 25(OH)D metabolite also circulates in the bloodstream bound to DBP. It is an abundant, but relatively inactive, vitamin D metabolite. Its circulating concentration provides the most readily available evaluation of the vitamin D status in a given individual. 25(OH)D must be further hydroxylated on a different carbon residue in the convoluted and straight portions of the proximal kidney tubule to gain hormonal bioactivity. Hydroxylation at position 1α by the mitochondrial cytochrome P450 enzyme 25-hydroxyvitamin D-1α-hydroxylase (CYP27B1) converts 25(OH)D to 1α,25-dihydroxyvitamin D [1,25(OH)$_2$D] (Fig. 58.1), the active, hormonal form of vitamin D that plays an essential role in mineral homeostasis, cellular differentiation, and bone mineralization.[16,17]

Upon reaching a target tissue, $1,25(OH)_2D$ binds a specific receptor (vitamin D receptor [VDR]) that is a member of the nuclear hormone receptor superfamily.[16-18] The VDR is considered a class II nuclear hormone receptor, because it needs to form a heterodimer with the retinoid X receptor (RXR) to bind specific DNA sequence elements with high affinity. These target sequences are termed vitamin D response elements, and the best characterized of these binding sites consist of two tandemly repeated hexanucleotide sequences separated by three base pairs.[18] Transcriptional coactivators and components of the basal transcriptional machinery interact with the liganded, DNA-bound VDR-RXR heterodimer to activate the transcription of vitamin D target genes responsible for carrying out the physiological actions of $1,25(OH)_2D$.[16,18] Amongst several target genes, the $1,25(OH)_2D$ hormone induces in target cells the expression of the gene encoding the key effector of its catabolic breakdown: 25-hydroxyvitamin D-24-hydroxylase (CYP24A1).[19,20] This ensures attenuation of the $1,25(OH)_2D$ biological signal inside target cells and helps regulate vitamin D homeostasis.

As detailed in this chapter, disease-causing mutations have been identified in genes encoding all components of this metabolic and signal transduction cascade: *CYP2R1*, *CYP27B1*, *VDR*, and *CYP24A1*.

KEY POINTS

- Disease-causing mutations have been identified in genes encoding all components of the vitamin D metabolic and signal transduction cascade: *CYP2R1*, *CYP27B1*, *VDR*, and *CYP24A1*.

RICKETS AND OSTEOMALACIA

The term "rickets" is often used to describe all of the skeletal abnormalities associated with defective mineralization in the growing skeleton, but it is more precise to restrict the term to changes in the growth plate and adjacent metaphysis. When mineralization is impaired, the accumulation of unmineralized osteoid at sites other than the growing metaphysis should be referred to as osteomalacia, not as rickets. Thus, defective mineralization can lead to both rickets and osteomalacia in the growing skeleton, but only to osteomalacia in the mature skeleton.

Rickets is characterized by the inadequate calcification of the growth plate and adjacent metaphysis. The impaired mineralization of the growth plate cartilage in the zone of provisional calcification prevents this zone from being resorbed. As the cartilage continues to be formed, but not resorbed, the growth plate begins to widen. Simultaneously, the trabecular bone directly underneath the cartilage fails to mineralize properly, and vascularization of this tissue becomes aberrant. These defects are accompanied by similar abnormalities in cortical bone, leading to the full spectrum of skeletal symptoms associated with the pathology.

Some nomenclature: "rickets resistant to vitamin D therapy" was described clinically by Albright et al. in 1937.[21] Subsequent reports[22,23] suggested a variant of resistant rickets that was fully clinically described by Prader et al. in 1961.[24] The absence of knowledge of the underlying molecular etiology of these diseases led to numerous, somewhat confusing designations: pseudo vitamin D–deficiency rickets,[24] vitamin D dependency,[25] vitamin D–dependent rickets type I, or 1α-hydroxylase deficiency.[26] In 1997, remarkable progress was made in the understanding of the molecular etiology of the disease through the identification of mutations in the gene encoding the 25-hydroxyvitamin D-1α hydroxylase (*CYP27B1*) in affected patients, leading to hydroxylation defects and the inability to synthesize $1,25(OH)_2D$.[27] For this reason, and to align with current Online Mendelian Inheritance in Man (OMIM) compendium nomenclature, we will use the OMIM designation of vitamin D hydroxylation–deficient rickets, type 1A (VDDR1A, OMIM 264700) to describe the disease.

On the other hand, VDDR1B (OMIM 600081) is caused by mutations in the *CYP2R1* gene[12-15] encoding the microsomal vitamin D 25-hydroxylase[28] and involves a defect in vitamin D 25-hydroxylation. Mutations in the *VDR* gene cause vitamin D–dependent rickets type 2A (VDDR2A, OMIM 277440), which is associated with true resistance to vitamin D action.[29] This condition was previously referred to as hereditary vitamin D–resistant rickets.

KEY POINTS

- Vitamin D hydroxylation–deficient rickets, type 1A (Online Mendelian Inheritance in Man compendium [OMIM] 264700) now designates mutations in the gene encoding the 25-hydroxyvitamin D-1α hydroxylase (*CYP27B1*) and replaces previous nomenclature for the disease (pseudo vitamin D–deficiency rickets, vitamin D dependency, vitamin D–dependent rickets type I, or 1α-hydroxylase deficiency).
- Vitamin D hydroxylation–deficient rickets, type 1B (OMIM 600081) is caused by mutations in the gene encoding the vitamin D 25-hydroxylase, *CYP2R1*.
- Vitamin D–dependent rickets, type 2A (OMIM 277440) is caused by mutations in the vitamin D receptor (nomenclature replaces hereditary vitamin D–resistant rickets).

VITAMIN D–DEFICIENCY RICKETS, VITAMIN D HYDROXYLATION–DEFICIENT RICKETS, AND VITAMIN D–DEPENDENT RICKETS

It is evident from the overview presented above that vitamin D metabolism can be affected at several levels: inadequate exposure to sunlight, inadequate dietary intake, and malabsorption of dietary vitamin D are classified as vitamin D–deficiency rickets. Reviews on these non-hereditary disorders of the vitamin D endocrine system have been published.[30-33] Genetic disorders affecting vitamin D metabolism and function leading to rickets or osteomalacia include impaired hepatic 25-hydroxylation, defects in renal 1α-hydroxylation, or defects in receptor function (Fig. 58.1).

The prime metabolic consequence of vitamin D deficiency is reduced net intestinal absorption of calcium.[1,2] Calcium malabsorption leads to a fall in plasma calcium, secondary hyperparathyroidism, reduced renal tubular reabsorption of phosphate, hypophosphatemia, and thus a reduction in the calcium X phosphate product. Eventually, deposition of mineral in osteoid is impaired because the supply of the relevant ions is reduced. The impaired mineralization triggers the development of the rachitic and/or osteomalacic phenotype.

Clinical Features of Vitamin D Hydroxylation–Deficient Rickets Type 1B

VDDR1B is a very rare condition that has been reported to affect six families to date.[12-15] It presents with later onset (~4 to 5 years of age) than VDDR1A and is characterized biochemically by hypocalcemia, hypophosphatemia, elevated parathyroid hormone (PTH), high alkaline phosphatase, and low-to-undetectable levels of 25(OH)D. Surprisingly, circulating concentrations of $1,25(OH)_2D$ are in the normal range or elevated. Radiographic findings include features of rickets, with classical cupping and fraying of the metaphyseal region and bowing of the legs. The serum biochemistry can induce misdiagnosis in the absence of genetic analysis: the low-to-undetectable 25(OH)D levels can be interpreted as classical nutritional vitamin D–deficiency

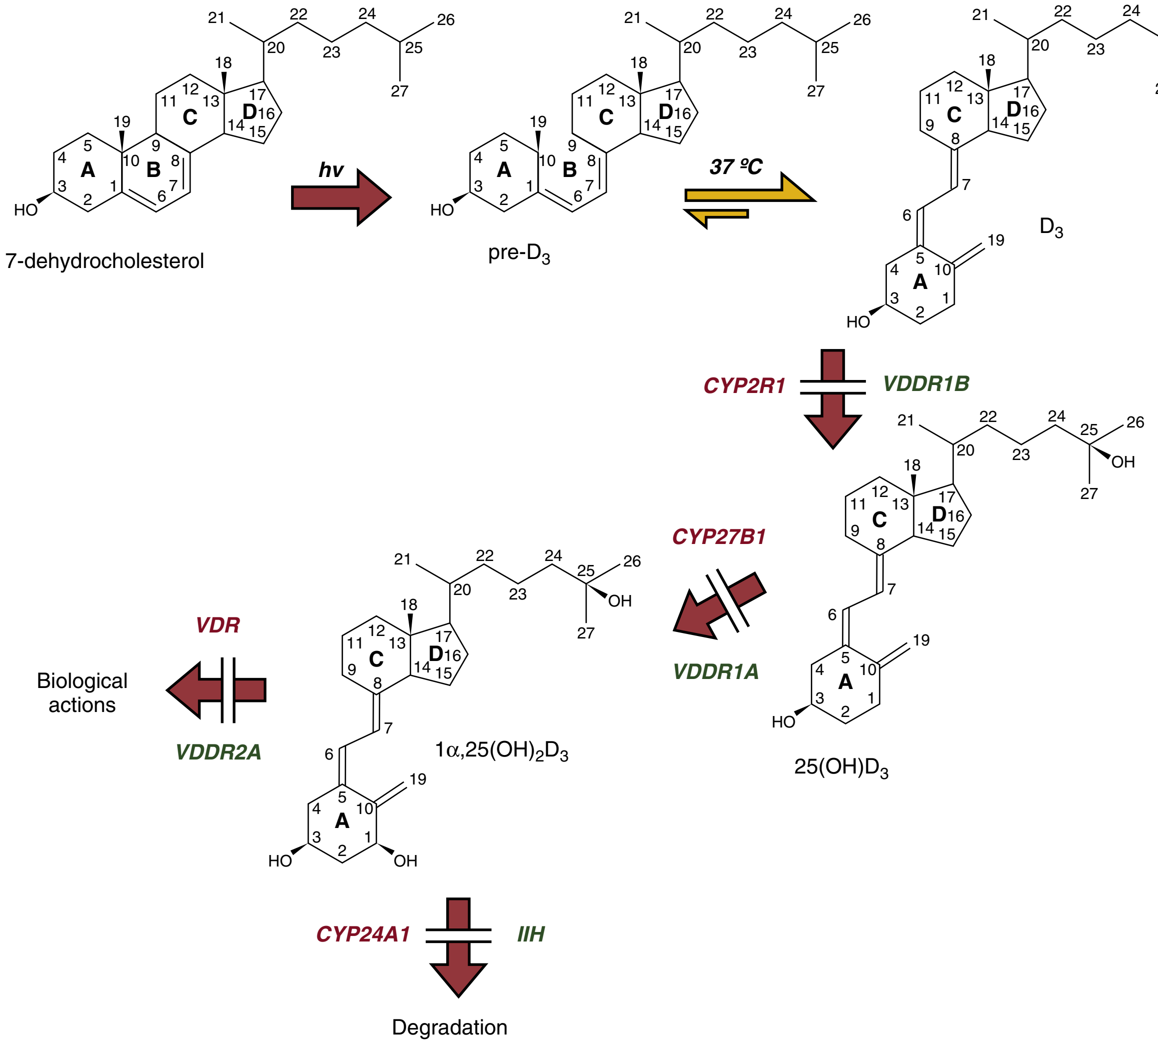

Fig. 58.1 Vitamin D metabolic pathway where genetic aberrations lead to rickets or hypercalcemia. Breaks in the arrows flanking CYP2R1, CYP27B1, VDR, and CYP24A1 represents the defects leading to VDDR1B, VDDR1A, VDDR2A, and IIH, respectively. *VDDR1A*, Vitamin D hydroxylation–deficient rickets type 1A; *VDDR1B,* vitamin D hydroxylation–deficient rickets type 1B; *VDDR2A*, vitamin D–dependent rickets type 2A; *IIH*, idiopathic infantile hypercalcemia; *VDR,* vitamin D receptor; *hv,* photon energy.

rickets, while the normal/high 1,25(OH)$_2$D levels can lead to diagnostic uncertainty.[14]

Clinical Features of Vitamin D Hydroxylation-Deficient Rickets Type 1A

The clinical symptoms of VDDR1A are similar to those of common vitamin D–deficiency rickets, including failure to thrive, hypotonia, and growth retardation. Affected babies lay supine because of severe muscle weakness and bone pain. At this age, gross skeletal deformities are rare; however, if diagnosis and treatment are delayed, severe deformities of the spine and long bones occur, together with generalized muscle weakness simulating myopathy. Motor problems translate into regression in head control and ability to stand. In some patients, the initial event is generalized convulsions, tremulations, and Bravais–Jacksonian fits or tetany. Pathological fractures may happen. The onset in most cases occurs early during the third trimester of life; the patients look healthy at birth.

Physical examination reveals a small, hypotonic child with wide anterior fontanel, frontal bossing, and frequent craniotabes (easy depression of the softened parietooccipital region). Tooth eruption is delayed, and erupted teeth show evidence of enamel hypoplasia. A rachitic rosary is either visible or palpable. In limbs, widening of the metaphyseal areas is evidenced by enlargement of wrists and ankles, and there is a variable degree of deformity (bowing) of long bones diaphyses. Deformities of the thorax may interfere with ventilation and predispose to pulmonary infection; infant death by pulmonary infections was not infrequent in the past when the diagnosis was either missed (confused with a neurological or respiratory condition) or made too late. The Chvostek sign (twitching of the upper lip upon light finger tapping of the facial nerve) reflects nerve irritability, a consequence of a rapid fall in serum calcium.

The x-ray features include diffuse osteopenia (mild to severe hypomineralization of the skeleton) and classic rachitic metaphyseal changes: fraying, cupping, widening, and fuzziness of the zone of provisional calcification immediately under the growth plate (Fig. 58.2). These changes are seen better and detected earlier in the most active growth plates, namely the distal ulna and femur and the proximal and distal tibia. Changes in the diaphyses may not be evident when metaphyseal changes are first detected. However, they will appear a few weeks later as rarefaction, coarse trabeculation, cortical thinning, and subperiosteal erosion. Looser–Milkman's pseudofractures and

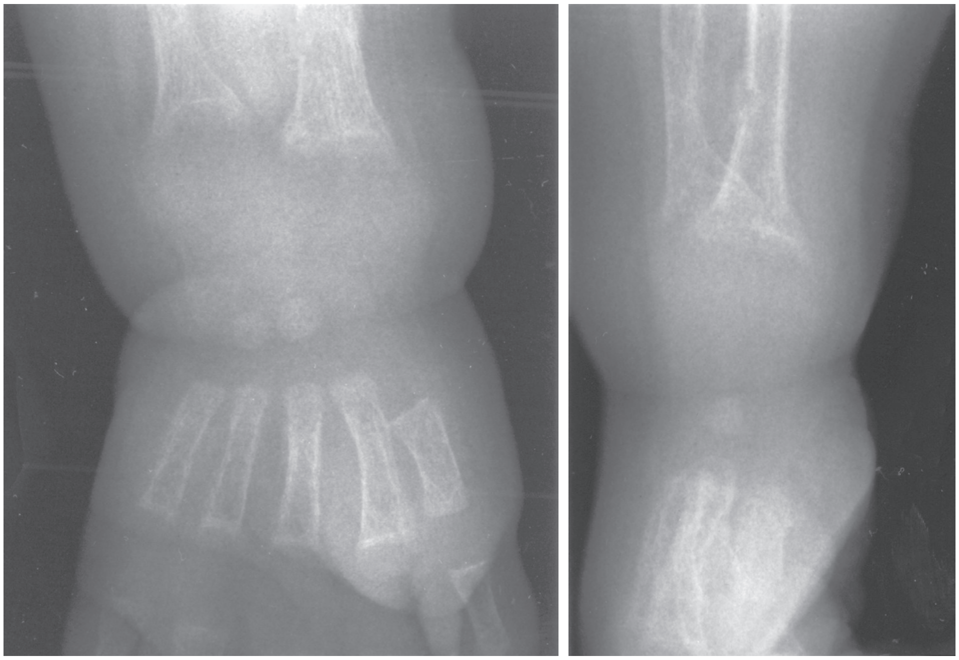

Fig. 58.2 Radiograph of the wrist of a 19-month-old boy with vitamin D hydroxylation–deficient rickets type 1A at diagnosis. Severe rickets and demineralization are evident. Pronounced hypocalcemia and secondary hyperparathyroidism were documented, with the latter causing a metaphyseal pseudofracture clearly seen on the lateral view.

curvature of the shafts of long bones may be observed, especially in children more than 1 to 2 years of age.

Hypocalcemia is the main biochemical feature in VDDR1A. A rapid decrease in serum calcium concentration may give rise to tetany and convulsions, which may occur before any radiological evidence of rickets. Prolonged hypocalcemia triggers secondary hyperparathyroidism and hyperaminoaciduria.[34] Urinary calcium excretion is very low, whereas fecal calcium is high as a consequence of impaired intestinal calcium absorption. Elevated urinary cyclic adenosine monophosphate is not a consistent finding, and normal values have been measured in VDDR1A patients despite high circulating PTH levels.[35]

Serum phosphate concentrations may be normal or low. When reduced, the hypophosphatemia is usually of a lesser degree than that measured in X-linked hypophosphatemic rickets.[36] It results from the combination of impaired intestinal absorption and increased urinary loss induced by the secondary hyperparathyroidism. Serum alkaline phosphatase activity is consistently elevated, and its increase precedes the appearance of clinical symptoms.

Patients with VDDR1A have normal serum levels of 25(OH)D after exposure to sunlight or oral intake of small doses of vitamin D; the concentrations increase if higher doses are given.[35] Circulating levels of 24,25-dihydroxyvitamin D [24,25$(OH)_2$D] are normal and correlate with those of 25(OH)D.[37] Serum levels of 1,25$(OH)_2$D are low to undetectable in untreated patients.[35,38] This is evident immediately after birth, months before any clinical evidence of rickets appears. Even when patients are treated with high doses of vitamin D, causing major increases in circulating levels of 25(OH)D, the blood concentration of 1,25$(OH)_2$D does not reach the normal range. These characteristic features of serum vitamin D metabolites have provided key insight into the pathogenesis of VDDR1A.

Clinical Features of Vitamin D–Dependent Rickets Type 2A

Many of the clinical findings in patients with VDDR 2A are identical to those described for VDDR1A, including bone pain, muscle weakness, hypotonia, and occasional convulsions.[39] Children are often growth-retarded, and tooth enamel hypoplasia is observed.[40] The radiological features of rickets are present. A major difference is that many children with VDDR2A have sparse body hair, and some have total scalp and body alopecia, sometimes even including eyebrows and eyelashes. Hair loss may be evident at birth or occur during the first months of life. Patients with alopecia generally have more severe resistance to vitamin D. In families with a prior history of the disease, the absence of scalp hair in newborns can provide initial diagnostic clues for VDDR2A. A defect in epithelial-mesenchymal communication that is required for normal hair cycling has been shown to be the cause of the alopecia in an animal model of VDDR2A.[41]

Serum biochemistry includes low concentrations of calcium and phosphate and elevated alkaline phosphatase activity. Secondary hyperparathyroidism with elevated circulating PTH is measurable. The key difference concerns circulating levels of vitamin D metabolites. The 25(OH)D values are normal, and, in the cases in which it has been measured, 24,25$(OH)_2$D levels have been low. Importantly, serum levels of 1,25$(OH)_2$D are elevated. This clinical feature clearly distinguishes VDDR2A from VDDR1A, where circulating concentrations of 1,25$(OH)_2$D are depressed. Additionally, patients with VDDR2A are resistant to supraphysiologic doses of all forms of vitamin D therapy. Table 58.1 outlines the similarities and differences between the forms of hereditary rickets involving the vitamin D endocrine system.

MOLECULAR ETIOLOGY OF VITAMIN D HYDROXYLATION–DEFICIENT RICKETS TYPE 1B

Several cytochrome P450 molecules have been shown to hydroxylate vitamin D on carbon 25,[8-11,28] but the identification of the most physiologically relevant enzyme remained uncertain for a considerable time. The initial main candidate was CYP27A1, which has some vitamin D 25-hydroxylase activity but mainly hydroxylates sterol carbons 26 and 27 to initiate bile acid synthesis.[42] Mutations in *CYP27A1* cause

TABLE 58.1 Genomic Defects and Clinical Manifestations of Vitamin D Hydroxylation–Deficient Rickets, Type 1B (VDDR1B), Vitamin D Hydroxylation–Deficient Rickets, Type 1A (VDDR1A), and Vitamin D-Dependent Rickets, Type 2A (VDDR2A)

Feature	VDDR1B	VDDR1A	VDDR2A
Mutations	*CYP2R1*	*CYP27B1*	*VDR*
Genetic inheritance	autosomal recessive	autosomal recessive	autosomal recessive
Age of onset	late (4–5 years of age)	early	early
Rickets	yes	yes	yes
Hypocalcemia	yes	yes	yes
Serum alkaline phosphatase	elevated	elevated	elevated
Secondary hyperparathyroidism	yes	yes	yes
Alopecia	no	no	yes
Serum 25(OH)D	low to undetectable	normal	normal
Serum $1,25(OH)_2D$	normal/high	low	elevated
Response to 25(OH)D therapy	yes	no	no
Response to $1,25(OH)_2D$ therapy	partial	yes	no

cerebrotendinous xanthomatosis, and patients with this disease or mice deficient for the *Cyp27a1* gene have normal calcium and vitamin D homeostasis.[43-45] These data suggested that enzyme(s) other than CYP27A1 must catalyze the 25-hydroxylation of vitamin D *in vivo*.

Cyp2r1 was identified as a gene encoding a cytochrome P450 vitamin D 25-hydroxylase using an elegant ligand activation assay strategy with a cDNA library from liver tissue of *Cyp27a1*-deficient mice.[28] Soon thereafter, mutations in both alleles of *CYP2R1* were identified in patients with low serum calcium concentrations, low circulating levels of 25(OH)D, and rickets.[12,46] These findings confirmed CYP2R1 as a physiologically relevant vitamin D 25-hydroxylase and identified *CYP2R1* mutations as the genetic defect in VDDR1B. The mode of transmission is autosomal recessive, although one family with matching clinical manifestations showed autosomal dominant transmission without *CYP2R1* coding sequence mutations, suggesting that different pathways may affect the function of the 25-hydroxylase enzyme.[47]

CYP2R1 Mutations

Since the identification and characterization of the first CYP2R1 mutation (p.L99P) in two patients of Nigerian origin,[13] four additional mutations in five other families of Nigerian, Saudi, French, and Moroccan descent have been reported in the literature (Table 58.2).[12,14,15] The type of mutations include frameshift (p.G42-L46delinsR and p.L257Sfs*6), missense (p.L99P and p.K242N), and splice site (c.367+1G>A). The splice donor mutation and the p.L257Sfs*6 mutation are predicted to yield truncated proteins that would be inactive, but have not been tested using expression strategies.[12] The p.K242N mutant showed decreased activity in a ligand activation assay with $1\alpha(OH)D$ as substrate.[15] The p.L99P and p.G42-L46delinsR mutations are devoid of enzymatic activity.[13,14]

An *in silico* approach was used to identify *CYP2R1* variants from publicly available databases and predict their pathogenicity. Mutations that were predicted as damaging by at least five separate computational tools yielded 22 potentially pathogenic *CYP2R1* mutations,[48] emphasizing that VDDR1B may be an underdiagnosed condition.[14]

TREATMENT OF VITAMIN D HYDROXYLATION–DEFICIENT RICKETS, TYPE 1B

Different therapeutic modalities have been attempted in patients with VDDR1B. Calcium supplementation alone showed poor efficiency.[15] High doses of vitamin D (cholecalciferol, D_3), with or without supplemental calcium, is able to cure rickets, but the blood biochemistry remains abnormal, mainly for elevated PTH and high alkaline phosphatase.[15] Treatment with $1\alpha(OH)D_3$ (alfacalcidol) and calcium is also beneficial, but the same abnormal biochemical indices are observed.[14] Success has been achieved by treatment of *CYP2R1*-deficient patients with $1,25(OH)_2D$, but this requires frequent monitoring to avoid hypercalciuria and nephrocalcinosis.[47]

Based on existing reports, and aligned with the concept of personalized medicine, the treatment of choice is replacement therapy with 25(OH)D to bypass the enzymatic defect. Such treatment leads to total amelioration in clinical symptoms and blood biochemistry data.[14] Replacement therapy administered to one genetically confirmed patient before symptoms appeared prevented bone deformation.[14]

An interesting finding associated with vitamin D or $1\alpha(OH)D_3$ therapy is the increase in circulating $1,25(OH)_2D$. Although it could be attributed to residual activity of the missense mutant CYP2R1 proteins, a preferred interpretation is redundancy of function from the many cytochrome P450 molecules that show 25-hydroxylase activity.[8-11] This is supported by studies in animal models where compound deletion of both *Cyp2r1* and *Cyp27a1* did not fully abrogate circulating levels of 25(OH)D.[49] The alternate enzymes appear not able to correct the metabolic defect in patients but may contribute to vitamin D metabolism in the context of high substrate availability.[14]

KEY POINTS

- The treatment of choice for vitamin D hydroxylation–deficient rickets, type 1B is replacement therapy with 25(OH)D to bypass the CYP2R1 enzymatic defect.

MOLECULAR ETIOLOGY OF VITAMIN D HYDROXYLATION–DEFICIENT RICKETS TYPE 1A

Serum levels of 25(OH)D are normal in untreated patients with VDDR1A and elevated in patients receiving large daily amounts of vitamin D.[35] These results indicate that intestinal absorption of vitamin D and its hydroxylation in the liver are not impaired in VDDR1A. Circulating levels of $24,25(OH)_2D$ are also normal and highly correlated with those of 25(OH)D, indicating a fully functional 25-hydroxyvitamin D-24-hydroxylase enzyme.[37] However, serum concentrations of $1,25(OH)_2D$ are low to undetectable in untreated patients and remain low even when they are treated with high doses of vitamin D.[35,38] This clearly identifies defective activity of the 25-hydroxyvitamin D-1α-hydroxylase enzyme (CYP27B1) as the basic abnormality in VDDR1A and differentiates it from VDDR1B and VDDR2A.

The CYP27B1 enzyme catalyzes the addition of an hydroxyl group at position 1α of the secosteroid backbone of 25(OH)D. The 1α-hydroxylase is a mitochondrial cytochrome P450 enzyme that requires electrons from NADPH to promote catalysis. These are delivered to the P450 moiety by the flavoprotein NADPH-ferredoxin reductase[50] and the nonheme iron protein ferredoxin.[51] The expression of these cofactors is ubiquitous, and their genes were mapped to chromosomes 17 and 11,[50,51] respectively, excluding them rapidly in the search for the VDDR1A mutations because the disease locus was mapped early on to chromosome 12.[52]

VDDR1A is inherited as a simple autosomal recessive trait.[25] No phenotypic abnormalities are observed in heterozygotes.[34] Although generally rare, VDDR1A may be more common in genetically isolated populations as a result of founder effects. For example, VDDR1A occurs at an unusually high frequency in the French Canadian population originating from the Charlevoix-Saguenay-Lac Saint Jean region of the province of Quebec.[53,54] Founder effects have also been reported for eastern Canadian (Acadian) patients[55] and for patients from Korea.[56]

Tremendous progress has been achieved in the study of the molecular etiology of VDDR1A through the cloning of the cDNA encoding for the CYP27B1 enzyme.[27,57-59] The human gene has also been cloned, sequenced, and mapped to 12q13.1-13.3 by fluorescence *in situ* hybridization,[58,60,61] consistent with the earlier mapping of the disease to this locus by linkage analysis.

The ultimate proof that mutations in the *CYP27B1* gene were responsible for the VDDR1A phenotype required the identification of such mutations in VDDR1A patients and carriers of the disease. The first identified mutation was reported by Fu et al.[27]; several additional mutations in various ethnic groups have since been published (Table 58.3). These findings unequivocally establish the molecular genetic basis of VDDR1A as inactivating mutation(s) in the *CYP27B1* gene. Further proof was provided by developing valid animal models of the disease using targeted inactivation of the *Cyp27b1* gene in mice.[62,63]

CYP27B1 Mutations

The human CYP27B1 enzyme is encoded by a single gene of nine exons and eight introns that is 5 kb in length.[64] The ferredoxin-binding domain is encoded by sequences contained in exons 6 and 7, while the heme-binding domain is contained in exon 8.[64,65]

At the time of updating of this chapter, 80 distinct *CYP27B1* mutations have been reported (Table 58.3). Identified disease-causing sequence changes include missense and nonsense mutations, deletions, duplications, and splice mutations.[27,56,60,61,66-87] These mutations are dispersed throughout the *CYP27B1* gene, affecting all exons and five introns (Table 58.3). There are a fair

[a] Nucleotide numbers refer to coding sequence (CDS; National Center for Biotechnology Information consensus CDS database CCDS8954.1) and are numbered from the translation start site. Amino acid replacement mutations are indicated according to codon number. Nomenclature follows standard mutation nomenclature in molecular diagnostics.[172] Reference indicates first report.

number of compound heterozygous mutations (different mutation on each *CYP27B1* allele) in affected patients. A frequent mutated allele is the 7-bp insertion (CCCACCC) in exon 8 (c.1325-1332ins7), present in several unrelated ethnic groups.[61,68,78-80] This mutation alters the downstream reading frame, causing a premature stop codon 16 bp downstream. One patient was also reported with a 9-bp insertion at the same position (c.1325_1334ins9), again causing a frameshift and further suggesting that this area is a mutational hot spot.[80]

A number of assays have been used to study the enzymatic activity of the missense CYP27B1 mutants, including expression of the recombinant protein in heterologous cells that express the electron carriers adrenodoxin reductase and adrenodoxin,[80] activation of vitamin D receptor–dependent gene transcription,[60,74] or enzymatic activity in peripheral blood mononuclear cells.[75,78] In the few cases where missense CYP27B1 mutant proteins retained residual capacity to hydroxylate 25(OH)D on carbon 1 (assayed by expressing the mutant cDNA in heterozygous cells), the VDDR1A patients exhibited mild clinical biochemistry changes.[66,81] However, most of the mutant proteins tested did not retain enzymatic activity, a surprising finding considering that residual amounts of $1,25(OH)_2D$ were measured in the serum of patients harboring the studied mutations.[74] Whether this reflects spurious 1α-hydroxylation of 25(OH)D by other cytochrome P450 proteins when CYP27B1 is defective, or detection of food-derived $1,25(OH)_2D$ is unclear.[74] Because of this absence of complete genotype-phenotype correlation, it has been suggested that vitamin D hydroxylation deficiency may be relatively more common than is currently appreciated.[88]

TREATMENT OF VITAMIN D HYDROXYLATION–DEFICIENT RICKETS, TYPE 1A

The treatment of choice is long-term (lifelong) replacement therapy with $1,25(OH)_2D_3$.[35,89,90] This results in rapid and complete correction of the abnormal phenotype, eliminating hypocalcemia, secondary hyperparathyroidism, and radiographic evidence of rickets. Strikingly, the myopathy disappears within days after initiation of therapy. The restoration of bone mineral content is equally rapid, and histological evidence of healing of the bone structure has been reported.[35] Correction of tooth enamel hypoplasia is only partial. An important aspect of treatment is to ensure adequate calcium intake during the bone healing phase. Needs can be monitored by frequent assessment of urinary calcium excretion. It should be noted that hypercalciuria is common during treatment with $1,25(OH)_2D_3$, particularly during the first year of administration. Its close monitoring is used to adjust the needs in $1,25(OH)_2D_3$. Although the initial dose is recommended to be 1 to 2 µg per day, the maintenance dose will vary between 0.5 and 1 µg per day. High levels of calcium excretion may amplify the pattern of calcium deposition in the kidney; thus, frequent renal imaging and assessment of renal function are essential during the course of treatment.

Before $1,25(OH)_2D_3$ became available from commercial sources, several investigators used the monohydroxylated analog $1\alpha(OH)D_3$,[91] which only requires liver hydroxylation at position 25 to be activated to the hormonally active metabolite. Remember that the 25-hydroxylation step is not affected by the VDDR1A mutation. Response to treatment with $1\alpha(OH)D_3$ is rapid, with healing of rickets in 7 to 9 weeks, and this compound is still used in several countries. On a weight basis, $1\alpha(OH)D_3$ is about half as potent as $1,25(OH)_2D_3$, nullifying any possible economic advantage in favor of the monohydroxylated compound.

KEY POINTS

- Vitamin D hydroxylation–deficient rickets, type 1a (VDDR1A) is inherited as a simple autosomal recessive trait; heterozygotes are not affected.
- Generally rare, VDDR1A may be more common in genetically isolated populations as a result of founder effects.
- The treatment of choice is lifelong replacement therapy with $1,25(OH)_2D_3$.

Molecular Etiology of Vitamin D–Dependent Rickets Type 2A

Patients with VDDR2A have normal 25(OH)D and low, but measurable, $24,25(OH)_2D$ serum values. The circulating levels of $1,25(OH)_2D$ are elevated from three to five times the normal values. These biochemical findings demonstrate that all the vitamin D metabolic enzymes (25-hydroxylase, 24-hydroxylase, and 1α-hydroxylase) are active in patients with VDDR2A. Most patients with the disease are resistant to all forms of vitamin D therapy. This lack of response to vitamin D treatment led Albright et al.[21] to introduce the concept of hormonal resistance. The molecular basis of vitamin D end-organ resistance became clearer as the mechanism of action of the hormonal form of vitamin D was elucidated.

Ligand-binding studies first established that the $1,25(OH)_2D$ hormone, like other sex steroid hormones studied at the time, binds to

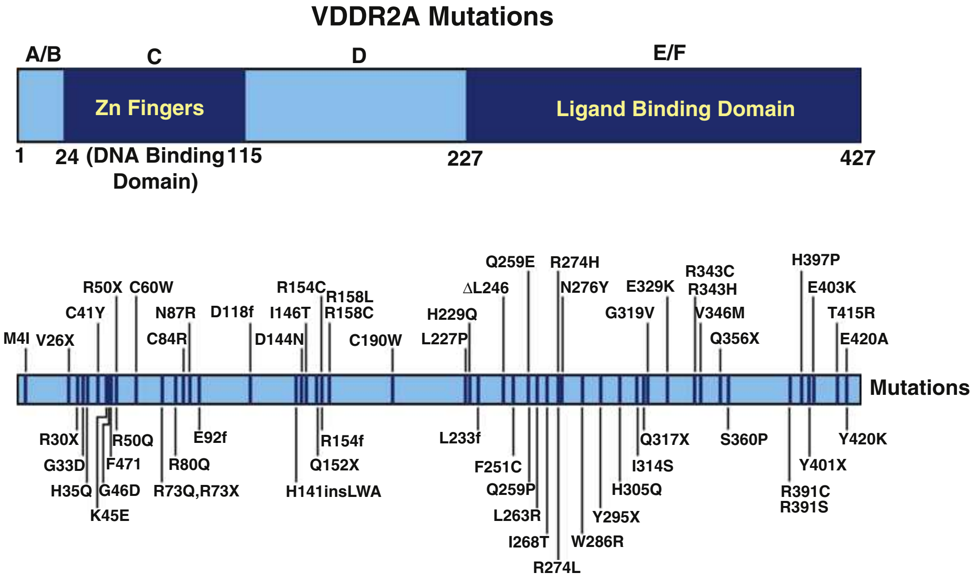

Fig. 58.3 Mutations associated with vitamin D–dependent rickets type 2A (*VDDR2A*). A schematic view of the vitamin D receptor is presented. The 427–amino acid protein can be separated into domains designated A/B, C, D, and E/F. Point mutations in human patients with VDDR2A are indicated below (one-letter amino acid code). *X*, Premature stop codon; *f*, frameshift mutation; *ins*, insertion.

a high-affinity receptor located in the nucleus.[92] It was later discovered that this receptor could bind to DNA.[93] This property was used to purify sufficient quantities of the VDR to raise antibodies.[94,95]

The observation that binding sites for 1,25$(OH)_2$D could be detected in many tissues in addition to the classical vitamin D target tissues helped to define the etiology of VDDR2A. Investigators began to study the VDR from cultured fibroblasts of patients and relatives, using ligand-binding assays, radio-immunoassays, and DNA-cellulose chromatography. Other fibroblast responses measured included induction of the 24-hydroxylase enzyme activity, and vitamin D-mediated growth arrest. These methodologies led to several milestone observations. In the first studies reported, $[^3H]$-1,25$(OH)_2D_3$ binding was undetectable in fibroblasts from VDDR2A patients, and high doses of 1,25$(OH)_2$D failed to induce the 24-hydroxylase bio-marker.[96] The diminished hormone binding provided a clear rationale for the end-organ resistance reported in these patients. Subsequent reports continued to describe a lack of response of the patients' cells to 1,25$(OH)_2$D, but some patients' fibroblasts exhibited normal $[^3H]$-1,25$(OH)_2D_3$ binding.[97] From these early reports, it was concluded that at least two classes of VDDR2A patients could be recognized: "receptor-negative" patients and "receptor-positive" patients. The development of a sensitive radio-immunoassay for the VDR protein[98] demonstrated that these semantic differences were incorrect. Using this assay, it was shown that fibroblasts from "receptor-negative" patients expressed normal levels of receptor protein. Pike et al.[99] hypothesized that the VDR defect in the patients' cells was because of a structural abnormality in the ligand-binding domain preventing $[^3H]$-1,25$(OH)_2D_3$ from binding to the receptor, and not from defective synthesis of the VDR protein. The two classes of VDDR2A were more adequately described by the terminology "ligand binding–positive" and "ligand binding–negative."

A second type of VDR structural abnormality was identified in cultured cells from patients displaying the "ligand binding–positive" VDDR2A phenotype. The VDR from these cells showed reduced affinity for heterologous DNA as measured by DNA-cellulose chromatography.[100] It was suspected that the defect in those patients would likely be a point mutation in the DNA binding domain (DBD) of the VDR.

Eventually, the purified receptor was used to obtain monoclonal antibodies that led to the cloning of the VDR cDNA from various species.[101-103] In turn, the structure of the *VDR* gene was analyzed. Eight exons comprise the entire coding region, spanning approximately 50 kb of genomic DNA.[29] The translation start site is contained within exon 2.

Analysis of the VDR cDNA sequence soon established that the VDR is a member of the nuclear hormone receptor superfamily, and its mechanism of action was subsequently unraveled.[104] The ligand-bound receptor forms a heterodimer with the RXR, and the dimer contacts specific sites within the regulatory domains of responsive genes. This results in positive or negative modulation of the transcription of target genes. The VDR is essential to transduce the biological effects of 1,25$(OH)_2$D, such as promoting calcium and phosphate transport across the small intestine and maintaining calcium homeostasis. The underlying molecular basis of the hormone resistance described in patients with VDDR2A is mutations in the VDR that render the receptor nonfunctional or less functional than the wild-type VDR. Several laboratories have independently engineered valid animal models of VDDR2A by inactivating the *Vdr* gene through gene targeting (reviewed in Bouillon et al.[105]).

VDDR2A follows an autosomal recessive pattern of inheritance. Parents of patients who are heterozygous for the mutation show no symptoms and have normal bone development. In many cases parental consanguinity is associated with the disease. Families often have several affected children, and males and females are affected equally.

Vitamin D Receptor Mutations

The VDR belongs to the nuclear hormone receptor superfamily. The different domains of nuclear receptors have been labeled A to F (Fig. 58.3). Some of these domains exhibit high sequence similarity between individual family members, while others vary considerably or are altogether absent. This diversity is manifested most strongly in domains A/B, D, and F. Domain A/B includes all residues that are N-terminal to the receptor's DBD. Domain C comprises the highly conserved zinc finger DBD, the hallmark feature of nuclear receptor family members. The DBD of the VDR consists of two zinc finger motifs located between residues 24 to 90. The zinc fingers are of the C2C2 type, with two zinc atoms tetrahedrally coordinated through four cysteine residues each that serve to stabilize the finger structure itself. The alpha-helical motifs residing on the C-terminal side of each zinc finger constitute the DNA-recognition and phosphate backbone–binding helices, respectively.[104] The region immediately C-terminal to the second zinc finger, covering residues 91 to 115, also forms an alpha-helical structure that could contribute to DNA contacts.

Region D serves as a flexible hinge domain between the DBD and domain E, and is the least conserved among nuclear receptors. The E region encodes the ligand-binding domain (LBD) of ligand-activated receptors and also contributes to transactivation and dimerization. The small F domain is not highly conserved between nuclear receptor family members.

The E/F region of the VDR (Fig. 58.3) represents a complex multifunctional domain involved in binding of the 1,25$(OH)_2$D ligand, heterodimerization with RXR, and transactivation. The structure of the LBD of the VDR has been modeled following x-ray crystallographic analysis.[106] It consists of 13 alpha-helices and several short β-strands organized as a "sandwich" around a lipophilic hormone-binding pocket. Once the ligand enters the pocket, a "lid" formed by Helix12 closes over the pocket. Several of the mutations characterized in VDDR2A coincide with hormone contact sites.

A number of different VDR mutations have been described in VDDR2A patients (Fig. 58.3 and Table 58.4). Interestingly, a mutation in the first translation initiation codon (p.M1T) is asymptomatic, as an in-frame methionine is encoded four codons downstream.[107] Some of the disease-causing genetic alterations are nonsense (X) or frameshift (fs) mutations that introduce premature stop codons in the receptor. The premature translation termination codons lead to truncated VDRs that lack the DNA-binding domain (R30X and R73X), the LBD (E92fs, Q152X, R154fs, L233fs, Y295X, and Q317X), or the AF-2 activation domain (Y401X); in most cases, the mRNAs for these truncated receptors are unstable.[108]

The first VDR mutation ever reported was described by Hughes et al.[29] and affected the DBD of the receptor. The mutation substitutes a polar uncharged glutamine for a positively charged arginine at position 73 (R73Q) within the second zinc finger of the DBD. The VDR mutation identified by Hughes et al.[29] was the first natural disease-causing mutation reported for the entire steroid-thyroid-retinoid receptor gene superfamily.

Several additional missense mutations affecting the DBD have been reported since (Table 58.4). Based on the crystal structure of the related GR, RXR, and TR molecules,[109-111] the H35Q, K45E, R50Q, R73Q, and R80Q mutations are thought to affect residues that contact DNA.[39,104,112] The conversion of residue glycine-46 to aspartic acid (G46D) introduces a bulky, charged amino acid that would create unfavorable electrostatic interactions with the negatively-charged phosphate backbone of the DNA helix.[113] The G33D mutation would be expected to have the same effect.[112] The F47I mutation is a relatively conserved substitution, but the loss of the phenylalanine ring structure may disrupt the hydrophobic core of the DBD and affect the proposed alpha-helical structure at the base of the first zinc finger.[112]

The first identified mutation affecting the LBD was the Y295X mutation reported by Ritchie et al.[114] This mutation truncates 132 amino acids from the C-terminus of the VDR, which results in the deletion of a major portion of the LBD. This mutation has been described in seven families forming a large kindred in which consanguineous marriages occurred.[108] The mutation was also identified in three additional families unrelated to the extended kindred.[115,116] As previously mentioned, the mutant mRNA is unstable, and the truncated VDR is undetectable using immunology-based assays.[108]

DBD, DNA-binding domain; *LBD*, ligand-binding domain.

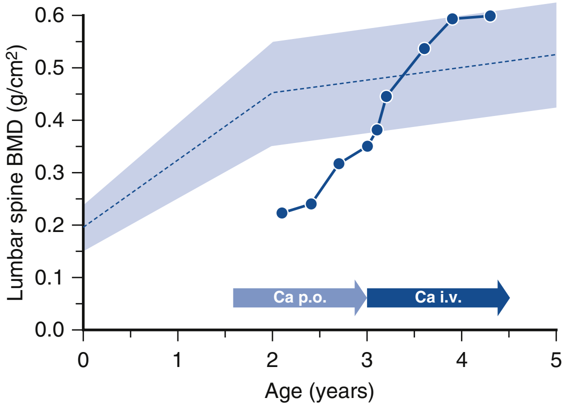

Fig. 58.4 Bone mineral density (*BMD*) response in a patient with vitamin D–dependent rickets type 2A treated with oral and intravenous calcium. BMD of the lumbar spine was measured by dual energy x-ray absorptiometry. The patient received oral calcium (Ca p.o., 2 grams/day) for 17 months before treatment with intravenous calcium (Ca i.v.). The shaded area represents the reference values for the corresponding ages. Note the rapid correction of the BMD upon initiation of intravenous calcium therapy.

The VDR crystallographic data[106] can be used to understand the structural consequences of the missense mutations in the VDR LBD described in VDDR2A patients. These mutations should perturb ligand binding and/or dimerization. Mutation E420K modifies a residue that provides coactivator dimerization interfaces, and thus results in loss of transactivation.[117]

TREATMENT OF VITAMIN D-DEPENDENT RICKETS, TYPE 2A

Therapies with pharmacological doses of vitamin D metabolites, including vitamin D itself, 25(OH)D, 1α(OH)D, and 1,25(OH)$_2$D have been used to attempt to overcome the target organ resistance to vitamin D associated with VDDR2A. Patients with VDDR2A without alopecia are generally more responsive to treatment with high doses of vitamin D preparations than patients with alopecia.[118] Doses reported effective range from 5,000 to 40,000 IU/day for vitamin D, 20 to 200 μg/day for 25(OH)D, and 17 to 20 μg/day for 1,25(OH)$_2$D.[119-121] The efficacy of treatment with high doses of vitamin D metabolites can be reconciled with the molecular cause of VDDR2A. When the resistance to vitamin D is caused by mutations in the VDR that moderately decrease the affinity of the receptor for its ligand, such as the H305Q or I314S mutations,[122,123] high doses of the hormone can apparently overcome the low-affinity binding defect and achieve adequate VDR occupancy to mediate normal 1,25(OH)$_2$D responses. A few patients with VDDR2A with alopecia have also been treated successfully using vitamin D metabolites.[29,97,124-128]

When vitamin D therapy is proven ineffective, intensive calcium therapy is the alternative treatment of choice. Some success has been achieved with high-dose oral calcium (Fig. 58.4).[129] To bypass the calcium absorption defect in the intestine caused by the mutant VDR, long-term intravenous (IV) calcium infusions should be considered (Fig. 58.4). High doses of calcium are infused IV during the night over a several-month period. The original protocol used a central catheter,[130] but success has been reported using intermittent peripheral IV administration.[131] Rapid disappearance of bone pains has been documented, as well as gradual improvement of calcemia and parathyroid function, followed by improvement of rickets (Fig. 58.5), and weight and height gains ensue.[130,132-134] The syndrome can recur when the IV infusions are discontinued.[130] After the serum calcium normalizes and radiological control of the rickets has been achieved with IV calcium infusions, high-dose oral calcium therapy is effective in maintaining normocalcemia.[133] For VDDR2A patients who do not respond to high-dose vitamin D therapy, the two-step calcium protocol (IV infusions followed by high oral doses) appears to be the preferred therapeutic approach.

It is interesting to note that there have been several reports of spontaneous improvement of disease in VDDR2A patients.[97,135,136] This spontaneous healing of rickets usually happens between 7 and 15 years of age, and has not been consistently associated with the onset of puberty. Spontaneous recovery does not appear to be related to treatment, as therapy was often ineffective, and improvement occurred after the treatment was discontinued. The patients appear to remain normocalcemic without therapy and show no evidence of rickets or osteomalacia. Spontaneous improvement has been reported for both ligand binding–positive and ligand binding–negative VDDR2A patients.[97,135,136] The alopecia persists despite healing of the rickets.[97,135,136] It is not uncommon for children to "outgrow" genetic diseases, and the organism appears able to compensate for the loss of VDR function after skeletal growth has been completed. This apparent functional redundancy does not apply to the hair follicle, however, a situation analogous to what has been described in the VDR-ablated animal model of the disease.[137]

KEY POINTS

- Vitamin D–dependent rickets, type 2A is autosomal recessive; individuals who are heterozygous for mutation in the vitamin D receptor show no symptoms and have normal bone development.
- Therapies with pharmacological doses of vitamin D metabolites are moderately effective when the mutation decreases the affinity of the receptor for its ligand.
- Long-term intravenous (IV) calcium infusion is the alternative treatment of choice. High doses of calcium are infused IV during the night over a several-month period.

IDIOPATHIC INFANTILE HYPERCALCEMIA

In a classic endocrine negative feedback loop, the vitamin D hormone, 1,25(OH)$_2$D, induces in target tissues the expression of the main effector of its catabolic breakdown, the CYP24A1 enzyme. This VDR-mediated transcriptional response ensures attenuation of the

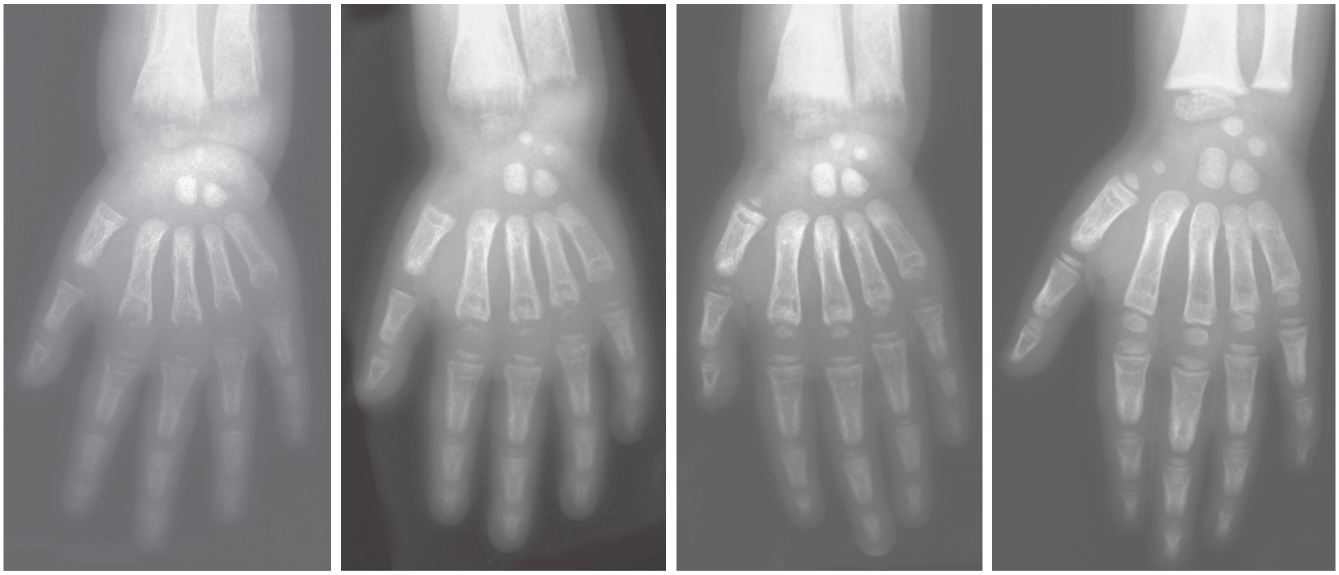

Fig. 58.5 Radiographic analysis of response to calcium therapy in a patient with vitamin D–dependent rickets type 2A. From left to right. First panel: at referral, the patient had been treated for 3 months with $1,25(OH)_2D_3$ (15 µg/day). Rickets is still active, and the bone is demineralized. Second panel: after 6 months on $1,25(OH)_2D_3$ (30 µg/day) and oral calcium (2 g/day), no significant improvement. Third panel: after 2 months of continuous intravenous calcium (without $1,25(OH)_2D_3$), mineralization is improved, but the growth plate remains irregular. Last panel: following 11 months of continuous infusion, mineralization is adequate. Clinical status is satisfactory and maintained with oral calcium (2 g/day).

$1,25(OH)_2D$ biological signal inside target cells and helps regulate vitamin D homeostasis. CYP24A1 is a mitochondrial inner-membrane cytochrome P450 enzyme that catabolizes $1,25(OH)_2D$ through modification of the secosteroid's aliphatic side-chain. The pathways catalyzed by the protein have been mapped out.[138]

Idiopathic infantile hypercalcemia[139-141] (IIH; OMIM 1438880, incidence of ~1 in 47, 000) was an orphan disease until Schlingmann et al.[142] identified loss-of-function mutations in the *CYP24A1* gene as the cause of the disease. IIH typically causes hypercalcemia and hypercalciuria in young infants. Those affected present with failure to gain weight, irritability, and nephrocalcinosis.[143-145] If undiagnosed, infants may die or remain stunted; they are also at risk for renal sequelae, including renal failure. Prompt intervention reduces these sequelae.[143-145] Hypercalciuria and risk of renal stones continue in most subjects throughout adult life.[143-145] Familial forms have been described; infant siblings of probands may be equally hypercalcemic without symptoms and are only detected by screening.[142,146] Moreover, the disorder may first manifest as hypercalciuria and painful kidney stones in adults, without childhood symptoms.[138,147-150]

The initial report of mutations in CYP24A1 causing IIH[142] was followed by various publications reporting the same consequences in adults,[149,151] including one in a 70-year-old male.[152] Thus the name of the disease is a misnomer because the cause is no longer unknown, and it is not confined to childhood.[153]

Molecular Etiology of Idiopathic Infantile Hypercalcemia

Schlingmann et al.[142] demonstrated biallelic mutations causing complete loss of function of CYP24A1 activity in European children with IIH. This leads to the symptoms of hypervitaminosis D: increased intestinal absorption of calcium and symptomatic hypercalcemia. Interestingly, not all cases of IIH are caused by *CYP24A1* mutations. In fact, there are at least three known diseases within the IIH constellation:

1. Loss-of-function mutations of *CYP24A1* at cytogenetic location 20q13.2 (sometimes known as Lightwood syndrome);[139]
2. Williams–Beuren Syndrome (WBS) caused by a large deletion on chromosome 7 (cytogenetic location 7q11.23) of 28 genes including the elastin gene (OMIM 194050); and
3. Loss-of function mutations of the sodium-phosphate cotransporter encoded at cytogenetic location 5q35.3 (also known as *SLC34A1*).[154]

It is likely that more genetic bases for hypercalcemia will be described in the future.

Because of this diagnostic uncertainty, the value of a reliable, rapid screening test for IIH has also been a principal research focus. Kaufmann et al.[155] described such a liquid chromatography tandem mass spectroscopy (LC-MS/MS) method for measuring $24,25(OH)_2D_3$ in 100 µL of serum or less, based upon derivatization with DMEQ-TAD, a dienophile that couples to all vitamin D metabolites in the blood. $24,25(OH)_2D_3$ is the main product of CYP24A1 found in the blood; it is indicative of the enzyme activity of the kidney enzyme and is roughly proportional to the level of the substrate $25(OH)D_3$. The absolute concentration of $24,25(OH)_2D_3$ is a fairly reliable measure of CYP24A1 enzyme activity *in vivo*, and the metabolite is low in most IIH patients with CYP24A1 mutations, even though most untreated IIH patients have elevated serum $25(OH)D_3$ values.[156] However, a more reliable indicator of IIH because of *CYP24A1* mutations is the ratio of the metabolite to its precursor $25(OH)D_3$, namely serum $25(OH)D_3$:$24,25(OH)_2D_3$.[155-158] We have found that this ratio is even more conclusive than serum $24,25(OH)_2D_3$ alone, because it eliminates the possibility that the patient might have a low serum $24,25(OH)_2D_3$ level because of vitamin D deficiency. Our experience of this analytical test using the serum $25(OH)D_3$:$24,25(OH)_2D_3$ ratio in over 100 IIH patients has convinced us that it does not produce false-negative results.[155,156] The other known causes of IIH, namely WBS mutations and sodium-phosphate cotransporter defects,[154] have normal serum $25(OH)D_3$:$24,25(OH)_2D_3$ ratios and are thus distinguished from CYP24A1 defects by this rapid test.

CYP24A1 Mutations

As of November 2021, there were 47 missense and deletion mutations of *CYP24A1* described in the literature (Table 58.5). These mutations must be

[a] Nucleotide numbers refer to coding sequence (NG_008334.1) and are numbered from the translation start site. Amino acid replacement mutations are indicated according to codon number. Nomenclature follows standard mutation nomenclature in molecular diagnostics.[172] Reference indicates first report.

distinguished from numerous polymorphisms of the CYP24A1 gene. Loss-of-function mutations can be predicted by various computer programs,[159] but comprehensive confirmation of their effects on enzyme activity only comes from expression of the defective gene. Schlingmann et al.[142] used site-directed mutagenesis of the wild-type human *CYP24A1* gene followed by transient or stable expression of the mutant in V-79 Chinese hamster lung fibroblasts and incubation of the cells with $[1\beta\text{-}^3H]1,25\text{-}(OH)_2D_3$ to demonstrate loss of enzyme activity. Others[150] have used cultured fibroblasts to show loss of CYP24A1 enzyme function. Molin et al.[156] used LC-MS/MS analysis of the $1,24,25\text{-}(OH)_3D_3$ product, instead of a radioactive substrate, to demonstrate loss of CYP24A1 enzyme activity.

CYP24A1 mutations can impact CYP24A1 structure and activity in different ways. Mutations are predicted to alter the substrate (e.g., p.L409S; p.L148P) or heme (e.g., p.R159Q; p.R396W; p.S334Vfs*9) binding site, to alter binding of the ferredoxin cofactor (e.g., p.E383Q), to alter access of the substrate or exit of the product (e.g., p.E143del), or generally to affect protein folding (e.g., p.E322K).[142,150,159-161]

Interestingly, a missense mutation predicted to cause loss of function (p.M245I) was detected in an asymptomatic child.[161] This asymptomatic child never received vitamin D supplementation,[161] which can unmask a latent IIH condition.[142] It is also possible that this mutation could cause late-onset manifestation of the disease or a latent phenotype. Along these lines, there have been several reports of adult patients presenting with mild/moderate degrees of hypercalcemia but recurrent nephrolithiasis or nephrocalcinosis.[147-151] Based upon gene frequency studies, Nesterova and colleagues estimate that the frequency of kidney stones in the general population because of *CYP24A1* mutations might be as high as 4% to 20%.[150]

TREATMENT OF IDIOPATHIC INFANTILE HYPERCALCEMIA

All IIH patients with *CYP24A1* mutations should be placed on restricted vitamin D intake, and female patients should be counseled on their increased risk of hypercalcemia during pregnancy. Successful treatments for acute hypercalcemic episodes in IIH have included use of general cytochrome P450 inhibitors such as ketoconazole and fluconazole that block many endogenous drug and steroidal hydroxylases, as well as CYP27B1.[150,162] These agents have significant side-effect profiles and the posology is cumbersome,[163,164] stimulating the search for improved therapies.

It has been reported that gain-of-function mutations in CYP3A4 result in enhanced bioinactivation of $1,25(OH)_2D$.[165] Based on this observation, pharmacologic intervention to enhance CYP3A4 expression has been tested to treat IIH.[166] Patients were treated with 10 mg/kg/d of rifampin, a potent inducer of CYP3A4.[167] The treatment was well tolerated and normalized or improved all clinical and biochemical parameters. Although additional testing is required, rifampin treatment presents an interesting alternative for inactivation of vitamin D metabolites in IIH.[166]

KEY POINTS

- Idiopathic infantile hypercalcemia (IIH) causes hypercalcemia, hypercalciuria, failure to gain weight, irritability, and nephrocalcinosis in young infants. Adult patients can present with mild/moderate degrees of hypercalcemia and recurrent nephrolithiasis or nephrocalcinosis.
- Female IIH patients are at risk of hypercalcemic episodes during pregnancy because of placental production of $1,25(OH)_2D_3$.
- Molecular etiology is mutation of the vitamin D 24-hydroxylase gene, *CYP24A1*, although other mutations can generate hypercalcemia symptoms. A reliable indicator of IIH because of *CYP24A1* mutations is the serum $25(OH)D_3{:}24,25(OH)_2D_3$ ratio.
- Treatments include restricted vitamin D intake and use of general cytochrome P450 inhibitors such as ketoconazole and fluconazole. Pharmacologic intervention with rifampin to induce CYP3A4 has shown promising results for inactivation of vitamin D metabolites in IIH.

FUTURE DIRECTIONS

Vitamin D homeostasis relies on the equilibrium between the activation of the vitamin D precursor and the catabolic breakdown of the hormonal 1,25(OH)$_2$D form. As we have seen, mutations in the enzymes regulating this pathway lead to metabolic bone disease. A new genetic form of vitamin D–dependent rickets was uncovered in two patients with mutations in the cytochrome P450 enzyme CYP3A4.[165] Although CYP3A4 was identified as a vitamin D 25-hydroxylase,[9] it was not this activation step that was perturbed in the patients. The unrelated subjects had early-onset rickets with reduced serum levels of 25(OH)D and 1,25(OH)$_2$D and did not respond to vitamin D or its activated forms. Characterization of the activity of the mutant enzyme showed that it oxidized 1,25(OH)$_2$D, with 10-fold increased activity over wild-type CYP3A4 and 2-fold greater activity than CYP24A1. The authors concluded that accelerated inactivation of vitamin D metabolites represents a mechanism for vitamin D deficiency and named the disease VDDR3.[165]

VDR-dependent gene transcription involves accessory molecules such as RXR, coactivators, and components of the basic transcriptional machinery.[17] It is also regulated by heterogeneous nuclear ribonucleoproteins (hnRNPs) that bind to vitamin D response elements to reduce gene transcription.[168,169] A patient with typical 1,25(OH)$_2$D resistance was found to have normal VDR sequence and function but suffered from overexpression of hnRNPs, notably hnRNPA1.[170,171] This form of genetic vitamin D–dependent rickets is classified as VDDR2B (OMIM 600785).

Conceptually, vitamin D resistance could also be the result of a mutation affecting other accessory proteins involved in 1,25(OH)$_2$D-dependent transcriptional activation, such as transcriptional coactivators.[16,17] As has happened with the examples discussed above, the identification and characterization of additional clinical manifestations of rickets or hypercalcemia may continue to further enhance our understanding of vitamin D biology.

  Familial Expansile Osteolysis, 1018
  Osteoprotegerin Deficiency, 1018

Endocrinologists not infrequently encounter patients who represent the great diversity of Mendelian disorders of the skeleton. Some of the entities are clinical curiosities, whereas some are lethal.[1,2] Some cause focal bony abnormalities, while some feature generalized disturbances of skeletal growth, modeling (shaping), and remodeling (turnover). Several derange mineral homeostasis. Cumulatively, the number of affected individuals is substantial. All of the disorders are also important because they reveal genes and gene products that influence skeletal biology.[2] As these conditions became understood molecularly, referrals to endocrinologists for diagnosis and treatment have increased. This chapter reviews several of the more common or instructive hereditary disorders of the skeleton, most manifesting in the pediatric population.

KEY POINTS

- Although each is rare, the many heritable diseases of the skeleton affect a significant number of individuals.
- Now, with revelation of the genetic bases of most of these disorders, their pathogeneses are better understood.
- Accordingly, such patients are increasingly referred to endocrinologists for diagnosis and treatment.

DENSE BONE DISORDERS

Increased bone density is a key feature of a number of heritable osteochondrodysplasias,[1-3] but sometimes occurs in various acquired endocrine, metabolic, dietary, hematologic, infectious, and neoplastic diseases (Table 59.1).[3] Osteosclerosis and hyperostosis refer to trabecular versus cortical bone thickening, respectively.[4] A radiographic skeletal survey will show where, and sometimes how, bone density increased, and often other characteristics necessary for diagnosis.[4] Now, the presumptive diagnosis is increasingly verified by mutation analysis.[1,2]

Osteopetroses

Osteopetrosis (OPT, or “marble bone disease”) was reported first by Albers-Schönberg in 1904.[5] Traditionally, two principal forms are encountered: the autosomal recessive infantile (malignant) type that, if untreated, is typically fatal during the first decade of life, and the autosomal dominant adult (benign) type, which has milder manifestations.[3] Especially rare, autosomal recessive childhood (intermediate) OPT has a less certain prognosis. Now, the genes underlying nearly all types of OPT are known, and molecular nosology has advanced the Mendelian classification.[6]

Although considerable clinical and genetic heterogeneity characterizes OPT,[1,6] all true forms reflect failure of osteoclasts to resorb skeletal tissue.[7] Persistence of primary spongiosa, calcified cartilage deposited during endochondral bone formation, is the histopathologic hallmark. The skeleton is fragile for several reasons.[3] Nevertheless, the term “*osteopetrosis*” is still sometimes used generically to describe radiodense skeletons. Now, OPT must be precisely applied based on this pathogenesis, partly because treating for other dense bone disorders could be unsuccessful or harmful.

Clinical Features. The manifestations and complications of OPT are largely predictable. Infantile OPT, which is caused by loss-of-function mutation in one of several genes,[1,6] manifests in the first years of life. There is a large head, frontal bossing, “adenoid” appearance, nystagmus, hepatosplenomegaly, short stature, and genu valgum. Nasal stuffiness caused by underdeveloped sinuses can be an early symptom. Cranial foramina do not widen, often compressing growing auditory, oculomotor, facial, and optic nerves. Blindness can also follow retinal degeneration or raised intracranial pressure. Hydrocephalus or sleep apnea may occur. Tooth eruption is delayed. Anemia, recurrent infections, and spontaneous bruising or bleeding are common and explained by myelophthisis from excessive bone tissue, osteoclasts, and fibrosis crowding what little marrow space has formed. Extramedullary hematopoiesis with hypersplenism and hemolysis may exacerbate

TABLE 59.1 **Dense Bone Diseases**

Dysplasias	Metabolic and Other
Central osteosclerosis with ectodermal dysplasia	Carbonic anhydrase II deficiency
Craniodiaphyseal dysplasia	Fluorosis
Craniometaphyseal dysplasia	Heavy metal poisoning
Dysosteosclerosis	Hepatitis C–associated osteosclerosis
LRP5/6 activation	Hypervitaminosis A, D
Van Buchem disease	Hyper-, hypo-, and pseudohypoparathyroidism
Sclerosteosis	Hypophosphatemic osteomalacia
Frontometaphyseal dysplasia	Milk-alkali syndrome
Juvenile Paget disease	Renal osteodystrophy
Infantile cortical hyperostosis (Caffey disease)	Axial osteomalacia
Lenz–Majewski syndrome	Fibrogenesis imperfecta ossium
Melorheostosis	Ionizing radiation
Metaphyseal dysplasia (Pyle disease)	Lymphoma
Mixed-sclerosing bone dystrophy	Mastocytosis
Oculodentoosseous dysplasia	Multiple myeloma
Osteodysplasia of Melnick and Needles	Myelofibrosis
Osteopathia striata	Osteomyelitis
Osteopetroses	Osteonecrosis
Osteopoikilosis	Paget disease of bone
Progressive diaphyseal dysplasia (Camurati–Engelmann disease)	Sarcoidosis
Pycnodysostosis	Skeletal metastases
	Tuberous sclerosis

(Modified from Whyte MP. Sclerosing bone disorders. In: Bilezikian JP, ed. *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism,* 9th ed. Hoboken, NJ: Wiley-Blackwell; 2019:826.)

already severe anemia. There is failure to thrive. Untreated patients succumb, usually during the first decade of life, to sepsis, pneumonia, severe anemia, or hemorrhage.

Intermediate OPT features macrocephaly and short stature, sometimes with cranial nerve palsies, ankylosed teeth leading to osteomyelitis of the jaw, fractures, and mild or occasionally moderately severe anemia. One type, carbonic anhydrase II (CA II) deficiency, the first OPT understood molecularly,[8] also features proximal or distal renal tubular acidosis (RTA) and cerebral calcification. Fractures, failure to thrive, developmental delay, and short stature can manifest in infancy or early childhood. Mental subnormality is common. Optic nerve compression and dental malocclusion are further complications. Metabolic acidosis presents as early as birth. The RTA, typically distal (type 1), may explain any hypotonia, apathy, and muscle weakness. Periodic hypokalemic paralysis can occur.[9]

Adult OPT (Albers–Schönberg disease) can fracture the axial as well as the appendicular skeleton, and sometimes cause blindness or deafness, facial nerve palsy, mandibular osteomyelitis, psychomotor delay, carpal tunnel syndrome, slipped capital femoral epiphysis, and osteoarthritis. Some asymptomatic "carriers" of one of the underlying chloride channel 7 gene (*CLCN7*) mutations[6] show no clinical or radiographic abnormalities.

Additional OPTs include enigmatic transient infantile OPT, which inexplicably resolves during the first months of life.[3] OPT, lymphedema, anhydrotic ectodermal dysplasia, and immunodeficiency (OL-EDA-ID) is an X-linked recessive disorder.[6] Additional severe OPTs feature epilepsy and neurodegeneration.[6] Dysosteosclerosis[1] is one of the "osteoclast-poor" types of OPT.[10]

Radiographic Findings. Typically, the three components of skeletal development are compromised: bone growth, modeling, and remodeling. Generalized symmetrical increase in bone density is the principal radiographic finding.[4] Cortical and trabecular bone are thickened. The calvarium is wide and dense, and the paranasal and mastoid sinuses are poorly pneumatized. Some bones, including vertebrae, may show a "bone-in-bone" (endobone) configuration. Rachitic changes can occur at physes if there is hypocalcemia.[11]

In CA II deficiency, findings can be subtle at birth. Remarkably, the subsequent osteosclerosis and defective skeletal modeling may diminish over years, perhaps from the accompanying RTA and metabolic acidosis. However, cerebral calcification appears on computed tomography between 2 and 5 years of age, affecting gray matter of the cortex and basal ganglia, and increases during childhood.[8]

In Albers–Schönberg disease, abnormalities appear during childhood, including an especially dense skull base, "rugger-jersey" spine, and sometimes enigmatic alternating sclerotic and lucent horizontal bands in the metaphyses of major long bones (Fig. 59.1). Defective modeling causes wide metaphyses with a club shape or "Erlenmeyer flask" appearance.[4] Pathologic "chalk-stick" fractures involve major long bones. Rarely, there is acroosteolysis, which is more common in pycnodysostosis.

Skeletal scintigraphy can reveal fractures and osteomyelitis. Magnetic resonance imaging helps assess hematopoietic stem cell transplantation treatment,[6] because engraftment restores medullary spaces and signals.[12]

Laboratory Findings. In infantile OPT, circulating calcium levels depend largely on gastrointestinal absorption because bone resorption is halted. Hypocalcemia can occur, especially if there is achlorhydria. The term osteopetrorickets denotes associated physeal widening.[11]

In adult OPT, biochemical indices of mineral homeostasis are usually within normal ranges, although circulating parathyroid hormone can be increased.

Numerous and dysfunctional osteoclasts explain why serum acid phosphatase and the "brain" isoenzyme of creatine kinase are often elevated.[13]

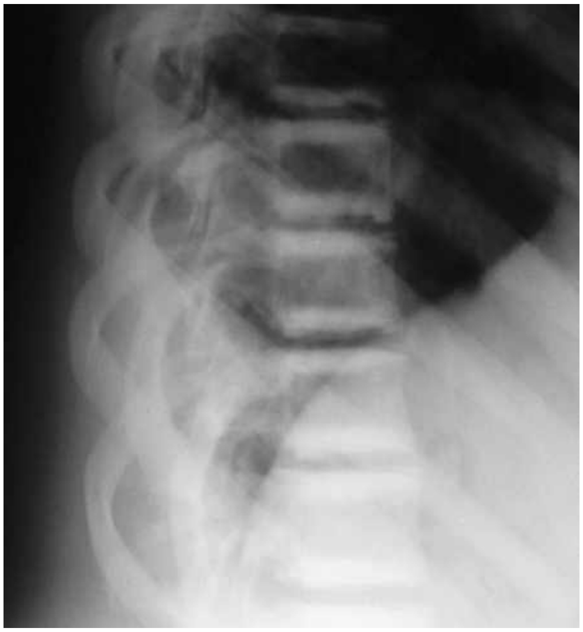

Fig. 59.1 **Osteopetrosis.** This teenage girl with Albers–Schönberg disease has a "rugger-jersey" spine typical of adult ("benign") osteopetrosis. The vertebral endplates are markedly thickened.

Histopathologic Findings. Osteoclast failure provides a pathognomonic finding in genuine OPTs,[7] that is, primary spongiosa synthesized during endochondral bone formation persisting as "islands" or "bars" of mineralized cartilage encased within trabecular bone. Osteoclasts are usually numerous, especially with many nuclei, but "ruffled borders" or "clear zones" may be absent. Fibrosis often crowds marrow spaces. Importantly, in several especially rare OPTs osteoclasts are few or absent.[6]

Etiology and Pathogenesis. The osteoclasts of most patients with OPT cannot produce hydrochloric acid for bone resorption because they harbor biallelic mutations of the *TCIRG1* (*ATP6i*) gene encoding the α3 subunit of the vacuolar proton (H+) pump, or mono- or biallelic defects of *CLCN7,* encoding chloride channel 7.[1,6] Whereas heterozygous mutations of *CLCN7* cause Albers–Schönberg disease, biallelic *CLCN7* mutations lead to severe or intermediate OPT.[14] Biallelic defects in *OSTM1* underlie especially severe OPT.[6] Mutations in *SNX10* have variable clinical severity.[15] OL-EDA-ID reflects disruption of an essential modulator of NF-κB.[1,6] Autosomal recessive transmission of mutations within the genes that encode receptor activator of nuclear factor-κB (RANK),[16] its ligand RANKL,[17] and SLC29A3, underlying dysosteosclerosis, cause the "osteoclast-poor" OPTs.

Ultimately, impaired skeletal resorption, and thus impaired bone modeling and remodeling, in OPT can cause both myelophthisis and bone fragility. The skeleton becomes brittle because calcified cartilage persists, collagen is not interwoven between osteons, hydroxyapatite "hardens," and microfractures may not heal.

Now, antiresorptive pharmaceuticals have become so potent that prolonged administration of excessive doses to a growing child can lead to the skeletal features of OPT.[18]

Treatment. Early prenatal diagnosis of OPT by sonography has generally been unsuccessful. Conventional radiographs occasionally reveal malignant OPT late in pregnancy. Now, mutation analysis is available, including in commercial laboratories, and can be used to detect OPT in utero.[6,19]

Because the etiology and pathogenesis for the failed osteoclast action and prognosis for the various OPTs differ, a precise diagnosis is crucial for planning therapy.[6,19] For example, infants or young children with CA II deficiency can have radiographic features of malignant OPT that then gradually resolve.[8] Now, diagnosis of OPT involves mutation analysis.[3,6,9]

Hyperbaric oxygenation can benefit osteomyelitis of the jaw. Surgical decompression of the optic and facial nerves may help some patients. Joint replacement is possible. Internal fixation may be necessary for femoral fractures.

Some success has been reported using a calcium-deficient diet. However, calcium supplementation would be necessary for accompanying hypocalcemic rickets.[11] Large oral doses of calcitriol to stimulate defective osteoclasts, together with dietary calcium restriction to prevent hypercalciuria/hypercalcemia, have not proven useful. Infusion of parathyroid hormone helped one infant.[3] Diminished cellular production of superoxide was the initial rationale for recombinant human interferon γ-1b (Actimmune) treatment,[20] now used supportively for malignant OPT before bone marrow transplantation.[6]

High-dose glucocorticoid treatment stabilizes pancytopenia and hepatosplenomegaly. One case report describes reversal of malignant OPT after prednisone therapy alone.[21] Prednisone and a low-calcium/high-phosphate diet may be helpful.[22]

CA II–deficiency RTA has been treated with bicarbonate, but the long-term impact is unknown.

Bone marrow transplantation from human leukocyte antigen (HLA)-identical donors has remarkably improved patients with infantile OPT, and cured some.[6,19] However, this approach is not always appropriate because it replaces dysfunctional osteoclasts through donor hematopoietic stem cell engraftment rather than correcting defects in osteoclastogenesis (e.g., RANKL deficiency).[17] Bone marrow transplantation corrects the OPT of CA II deficiency and slows the cerebral calcification, but does not address the RTA.[23] Because severely crowded medullary spaces appear less likely to engraft, rapid molecular diagnosis and early intervention seem best.[24] Marrow from HLA-nonidentical donors is having improved success.[6] Progenitor cells from cord blood have been useful.[25] Marked hypercalcemia can occur as osteoclast function begins.

KEY POINTS

- "Osteopetrosis" now refers selectively to the dense bone disorders that result from generalized failure of osteoclasts to resorb skeletal tissue.
- "Malignant (infantile)" and "benign (adult)" osteopetrosis imprecisely describe such entities, which are increasingly classified by mutation analysis.
- Distinguishing the especially rare "osteoclast-poor" from "osteoclast-rich" osteopetroses is crucial when considering treatment using hematopoietic stem cell transplantation.

Pycnodysostosis

Most reports of pycnodysostosis have been from the United States or Europe, but its prevalence seems greatest in Japan. Parental consanguinity explains approximately 30% of cases. The etiology is biallelic mutation of the *CTSK* gene that encodes cathepsin K.[26]

Clinical Features. In infancy or early childhood there is disproportionate short stature, a relatively large cranium with frontooccipital prominence, small facies and chin, proptosis, bluish sclera, beaked nose, high-arched palate, obtuse mandibular angle, and dental malocclusion with retained deciduous teeth.[27] The anterior fontanel and

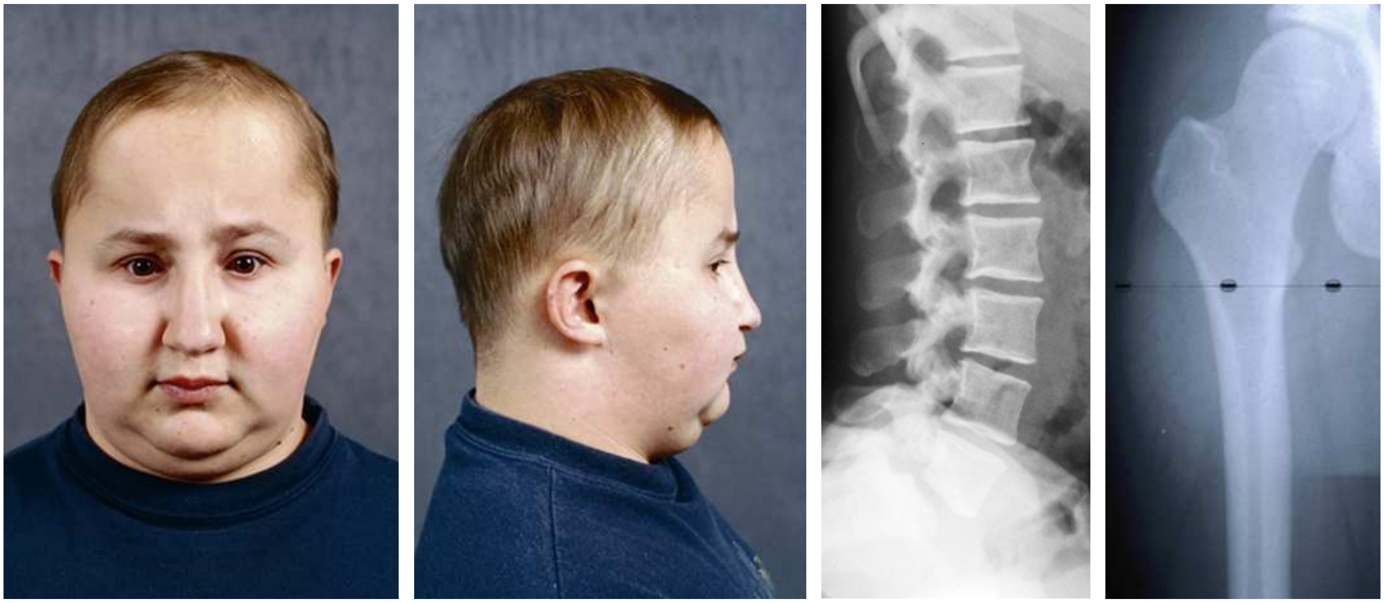

Fig. 59.2 **Kenny–Caffey Syndrome.** This 20-year-old man with Kenny–Caffey syndrome has mild brachycephaly, increased biparietal diameter, bifrontal narrowing, prominent zygomas, hypotelorism, and microretrognathia. His skeleton is diffusely osteosclerotic and hyperostotic.

cranial sutures remain open. Hands are small and square, with short and clubbed fingers from acroosteolysis or aplasia of terminal phalanges. Adult height ranges from 4 feet 3 inches to 4 feet 11 inches. Recurrent fractures typically involve the lower limbs and cause genu valgum deformity, although affected individuals usually walk independently. Pectus excavatum may occur. Respiratory infections and right heart failure can reflect upper airway obstruction from micrognathia. Approximately 10% of patients have compromised mentation.[27]

Radiographic Findings. Pycnodysostosis resembles most OPTs by manifesting recurrent fractures with generalized uniform osteosclerosis in childhood that increases with age. The calvarium and skull base are sclerotic, and the orbital ridges are dense. Although long bones have narrow medullary canals, striking modeling defects, endobones, and radiodense striations are absent. Distinguishing findings include delayed closure of cranial sutures and fontanels (prominently the anterior), wormian bones, obtuse mandibular angle, and hypoplastic facial bones, sinuses, distal phalanges, ribs, and lateral gracile clavicles.[4] Vertebral bodies are dense, with anterior and posterior concavities, but transverse processes are uninvolved. Lumbosacral spondylolisthesis as in the OPTs is not uncommon, and there can be lack of segmentation of the atlas and axis.

Laboratory Findings. Anemia is not expected. Serum calcium, phosphate, and alkaline phosphatase are usually normal. Cortical bone histopathology features diminished activity of osteoblasts and osteoclasts.[28] Abnormal inclusions are found in chondrocytes. Electron microscopy suggests impaired degradation of collagen.[28]

Cause and Pathogenesis. *CTSK* encodes cathepsin K, a lysosomal cysteine protease that is highly expressed in osteoclasts.[29] Thus, pycnodysostosis can be considered an OPT, because impaired collagen degradation by osteoclasts is a fundamental pathogenetic defect. Bone remodeling, and therefore quality, is compromised. Additionally, circulating monocytes have defective killing activity and interleukin-1 secretion. Virus-like inclusions in osteoclasts[30] and defective growth hormone secretion with low circulating insulin-like growth factor 1 levels[31] have been reported.

Treatment. There is no established medical therapy for pycnodysostosis.[32] Marrow cell transplantation has not been reported. The orthopedic challenges have been briefly reviewed.[33] Long bone fractures are typically transverse and heal at a satisfactory rate, but delayed union and massive callus formation can occur. Intramedullary fixation of long bones is formidable because of their hardness.

Extraction of teeth is difficult, and mandibular fracture has occurred.[27] Osteomyelitis of the jaw may require antibiotic and surgical treatment. Severe obstructive sleep apnea can be treated with upper airway surgery together with positive pressure ventilation.

Kenny–Caffey Syndrome

Kenny–Caffey syndrome features marked short stature, delayed closure of fontanels, frontal bossing, triangular face, small eyes (Fig. 59.2), defective dentition, dense bones, and often recurrent hypocalcemia with low serum parathyroid hormone levels.[1] Inheritance is usually autosomal dominant, involving heterozygous mutations of *FAM111A*, although an autosomal recessive form reflects biallelic mutation of *TBCE*.[1,34]

Progressive Diaphyseal Dysplasia (Camurati–Engelmann Disease)

Progressive diaphyseal dysplasia (PDD), an autosomal dominant disorder, is caused by activating mutations in *TGF-β1*.[35]

Clinical Presentation. PDD typically presents during childhood with limping or a broad-based and waddling gait, as well as lower limb pain, muscle wasting, and diminished subcutaneous fat mimicking a muscular dystrophy (Fig. 59.3). However, the clinical and radiographic expressivity is wide-ranging.[36] In severe occurrences, osteosclerosis also involves the skull and axial skeleton, and these patients have a characteristic body habitus featuring an enlarged head with prominent forehead, proptosis, and thin limbs with thickened bones. Cranial nerve palsies can develop. Raised intracranial

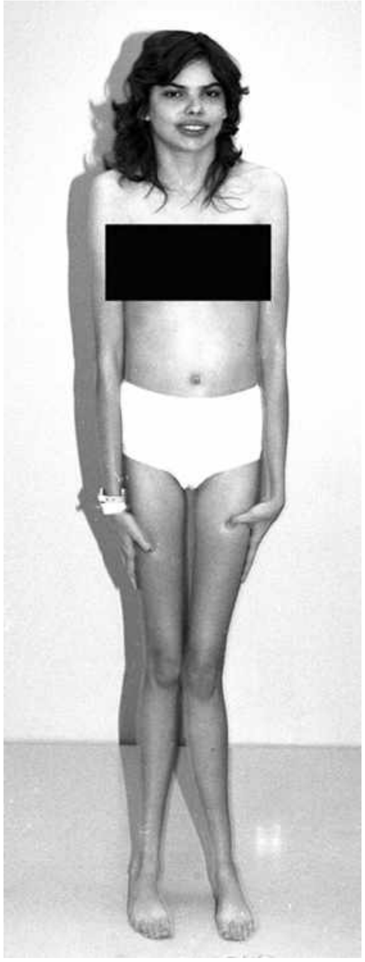

Fig. 59.3 **Progressive diaphyseal dysplasia.** This 16-year-old woman with Camurati–Engelmann disease has characteristic sarcopenia, most evident in her lower limbs, where there is knock-knee deformity.

pressure may occur. Puberty is sometimes delayed, and some patients are unusually tall. Bony thickening with skeletal tenderness is palpable. Hepatosplenomegaly, as well as Raynaud's phenomenon, can suggest vasculitis.[37] The course is variable, and symptom remission sometimes occurs in adult life.

Radiologic Features. Painful hyperostosis gradually involves the periosteal and endosteal surfaces of major long bones. Radiographic studies of PDD typically show progressive disease during growth.[4] Age of onset, rate of progression, and degree of bony involvement are highly variable. Tibias and femurs are most often involved; less frequently the humeri radii, ulnae, or short tubular bones. Diaphyses gradually widen and develop irregular surfaces. Bone sclerosis is fairly symmetrical and spreads to involve metaphyses, yet the epiphyses are characteristically spared (Fig. 59.4). The clavicles, scapulae, and pelvis may also thicken. Maturation of the new bone increases the hyperostosis. However, in severely affected children, some skeletal areas can appear osteopenic. In mild PDD, scintigraphic abnormalities may be confined to the lower limbs. Clinical, radiographic, and scintigraphic findings are generally concordant.[38] Occasionally, however, bone scans are unremarkable despite marked radiographic changes. This seems to reflect advanced but quiescent disease. Sometimes there are no radiographic changes, yet bone scintigraphy is abnormal. This can represent early skeletal involvement.

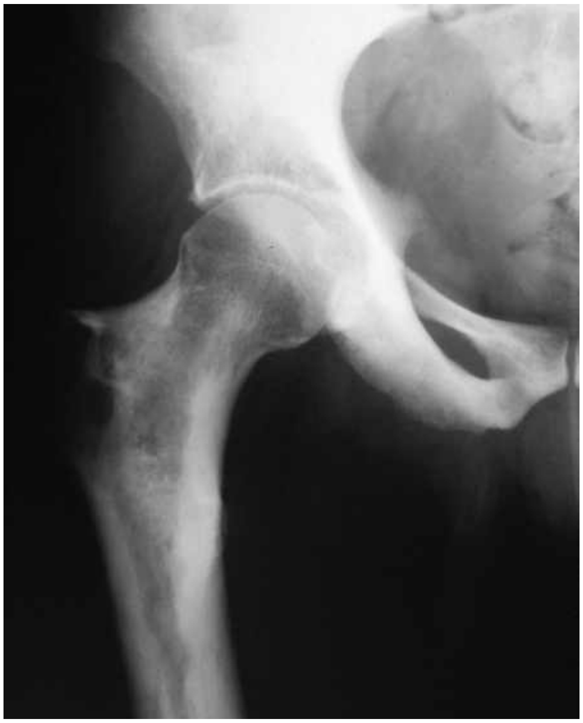

Fig. 59.4 **Progressive diaphyseal dysplasia.** This man with Camurati–Engelmann disease has in his proximal femur irregular hyperostosis that characteristically does not extend to the ends of long bones.

Laboratory Findings. Routine biochemical parameters of bone and mineral metabolism are typically normal in PDD, although serum alkaline phosphatase activity can be elevated. Mild hypocalcemia and significant hypocalciuria may occur in severe disease, likely reflecting positive calcium balance.[39] When present, mild anemia and leukopenia and an elevated erythrocyte sedimentation rate seem to reflect a poorly characterized systemic disturbance.[37]

Skeletal histopathology shows that new bone formation along the diaphysis is disorganized woven bone that matures with incorporation into the cortex. Electron microscopy has revealed myopathic changes and vascular abnormalities.

Etiology and Pathogenesis. The etiology of PDD is heterozygous mutation within a specific region of TGF-β1 that compromises dimerization and stability of the latent TGF-β1 complex, keeping this enhancer of bone formation active.[40] The clinical and laboratory features of severe PDD and its responsiveness to glucocorticoid treatment suggest an inflammatory connective tissue disease.[37] Excess active TGF-β1 in the marrow, released by osteoclasts, may induce migration,[41] yet aberrant differentiation,[42] of osteogenic stem cells.

Treatment. PDD is a chronic and somewhat unpredictable disorder. Symptoms may remit during adolescence or adult life. Management of cranial base hyperostosis has been reviewed.[43] Glucocorticoid therapy, typically small doses of prednisone on alternate days, can relieve bone pain and improve bone histology.[44] Bisphosphonate therapy can increase skeletal pain,[45] which may instead be controlled with salmon calcitonin nasal spray.[46]

Infantile Cortical Hyperostosis (Caffey Disease)

Infantile cortical hyperostosis features focal self-limiting, massive, subperiosteal new bone formation, typically of the long bones, mandible, or clavicles, together with fever, soft tissue swelling, and irritability.[47] A heterozygous missense mutation has been found in *COL1A1* that encodes type 1 collagen.[48]

Endosteal Hyperostoses

These are rare, highly informative, Mendelian disorders that feature excesses of good-quality cortical bone.[49] Van Buchem and associates in 1976 described *hyperostosis corticalis generalisata*.[50] Subsequently, additional hyperostoses involving primarily endosteal surfaces were characterized.[49]

Van Buchem disease is an autosomal recessive disorder[50] that is rarer than case reports might suggest. The principal clinical feature is marked progressive asymmetrical thickening of the jaw during puberty. The mandible develops a wide angle, yet there is no prognathism, and dental malocclusion is uncommon. There may be no symptoms, but cranial sclerosis develops as early as infancy, often causing recurrent facial nerve palsy, deafness, and optic atrophy from narrowing of cranial foramina. Long bones may hurt when palpated, yet are strong.[50] Endosteal cortical thickening leads to homogeneously dense diaphyses with narrowed medullary canals, yet long bones appear properly shaped. Osteosclerosis affects the skull base, facial bones, vertebrae, pelvis, and ribs.[4] There may be hyperphosphatasemia from bone, but serum calcium and phosphate levels are normal. Glucocorticoid therapy may be useful.[51]

Sclerosteosis, like Van Buchem disease, is an autosomal recessive disorder most prevalent in people of Dutch ancestry. Affected individuals additionally have congenital bony or soft tissue syndactyly and are excessively tall. At birth, only bony fusion of the middle and index fingers may be noted. During early childhood, skeletal overgrowth involves especially the skull, causing facial disfigurement. Progressive bone thickening widens the jaw resulting in prognathism.[52] Intelligence is normal. Deafness and facial palsy are significant complications. A small skull vault may increase intracranial pressure, cause headaches, and compress the brainstem,[53] shortening life expectancy.[54] Radiographs show long bones that widen as cortices thicken. Vertebral pedicles, ribs, and the pelvis may become dense. Middle ear ossicles can fuse, with narrowing of the internal auditory canal and cochlear aqueduct. No abnormality of mineral homeostasis or of pituitary function has been documented.

Deactivating mutations of the gene *SOST*, which encodes the inhibitor of bone formation sclerostin, cause sclerosteosis, type 1.[1,55] Van Buchem disease results from a 52-kb deletion of a downstream enhancer of *SOST*.[56] Thus, these disorders compromise the quality or amount, respectively, of sclerostin. Mutations in the portion of *SOST* that encodes the secretion signal cause autosomal dominant craniodiaphyseal dysplasia.[57] Sclerosteosis type 2 involves mutation of *LRP4*.[58]

Healthy sclerostin disengages low-density lipoprotein receptor–related protein (LRP) 5 and 6 from canonical Wnt signaling.[59] Deficient inhibitory action of sclerostin in these disorders enhances bone formation by osteoblasts, with failure of osteoclasts to compensate.[53]

There is no specific medical treatment for these four endosteal hyperostoses. Surgical correction of bony syndactyly is difficult. Management of the neurologic dysfunction, including craniectomy, has been reviewed.[53]

Worth type endosteal hyperostosis,[60] now called "high bone mass,"[61,62] is an autosomal dominant disorder that, like sclerosteosis types 1 and 2, Van Buchem disease, and craniodiaphyseal dysplasia, increases WNT/β-catenin signaling, leading to excessive high-quality bone formation. The etiology is gain-of-function mutation of *LRP5* or *LRP6* encoding the cognate LRP5 and LRP6 receptors, respectively.[62,63] LRP5 high bone mass is no longer incorrectly considered a type of autosomal dominant OPT.[64] In one view, LRP5 activation decreases systemic serotonin thereby enhancing bone formation.[65] However, it is generally accepted that compromised sclerostin binding to LRP 4, 5, or 6 activates WNT/β-catenin signaling and osteoblast activty.[66] LRP5 and 6 high bone mass can cause cranial nerve palsies, skeletal pain, and oropharyngeal exostoses.[62,67]

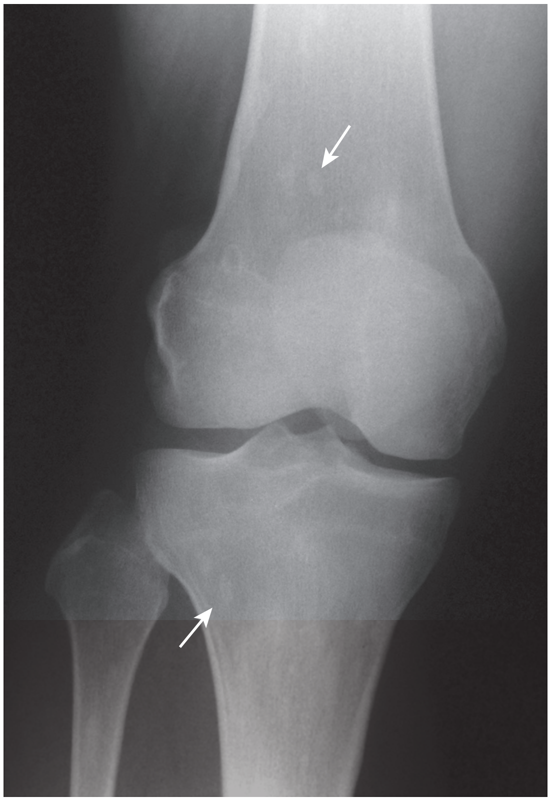

Fig. 59.5 **Osteopoikilosis.** Faint round or oval areas of osteosclerosis *(arrows)* are present in the metaphysis of the distal femur and proximal tibia.

Osteopoikilosis

Osteopoikilosis (spotted bones) is usually a radiographic curiosity transmitted as a highly penetrant autosomal dominant trait.[68] However, joint contractions and limb length inequality can occur, especially if there are radiographic changes of melorheostosis ("dripping candle wax bone").[69] When connective tissue nevi called *dermatofibrosis lenticularis disseminata* are present, this is Buschke–Ollendorff syndrome.[70] The spotted bone is benign and asymptomatic, but if misunderstood can lead to investigation for metastatic disease. Hence, family members at risk should be counseled. Radiographs show numerous small foci of usually round or oval osteosclerosis[4] involving the ends of short tubular bones, the metaepiphyseal regions of the long bones, and the tarsal, carpal, and pelvic bones (Fig. 59.5). Radionuclide accumulation is not increased on bone scanning.[71] These thickened trabeculae or islands of cortical bone do not change over decades.

The nevi usually appear before puberty on the lower trunk or extremities and are small, asymptomatic papules or yellow or white discs or plaques, deep nodules, or streaks. They represent excessive, unusually broad, and markedly branched elastin fibers in the dermis.[70] Heterozygous deactivating mutations in the *LEMD3* gene cause osteopoikilosis and the Buschke–Ollendorff syndrome,[72] but there may be genetic heterogeneity.[73] LEMD3 is an inner nuclear membrane protein that antagonizes TGF-β1 and bone morphogenetic protein signaling.

Osteopathia Striata

Osteopathia striata features gracile linear striations of trabecular bone, especially in the metaepiphyses of major long bones and in the periphery of the iliac bones, that are unchanged for years.[4] Radionuclide accumulation is not increased during bone scanning.[71] It is a curiosity when an isolated autosomal dominant finding, but also occurs in several clinically important syndromes, including osteopathia striata with cranial sclerosis,[74] where cranial nerve palsies are common because of *WTX* gene mutations.[75] Osteopathia striata with focal dermal hypoplasia (Goltz syndrome) is an X-linked dominant disorder complicated by bony defects in the limbs and widespread linear areas of dermal hypoplasia through which adipose tissue herniates because of mutation of the *PORCN* gene.[76]

Pachydermoperiostosis

Pachydermoperiostosis (hypertrophic osteoarthropathy: primary or idiopathic) manifests a classic clinical triad of hyperhidrosis, clubbing of the digits, and thickening of the skin, especially of the face and forehead (*cutis verticis gyrata*).[77] However, some affected individuals have one or two of these findings. Autosomal dominant inheritance with variable expression is established,[77] but autosomal recessive transmission also occurs.[78] Black people seem more severely affected than White people, and men more so than women. Presentation is typically during adolescence, but variable.[77] Symptoms emerge over a decade, but can then abate. Progressive enlargement of the hands and feet may cause a "pawlike" appearance. Palms may be dripping wet. Arthralgias of the elbows, wrists, knees, and ankles are common. Stiffness of the appendicular and axial skeleton can develop, and cranial or spinal nerves can become compressed. Fatigue is common. Cutaneous changes include coarsening, thickening, furrowing, pitting, and oiliness of especially the scalp and face, with some affected individuals described as "acromegalic." Myelofibrosis, myelophthisic anemia with extramedullary hematopoiesis, and renal amyloidosis may occur.

Radiologic Features. Radiographs reveal periosteal new bone formation, especially in the distal limbs, that roughens the surface of cortical bone.[4,79] The radius, ulna, tibia, and fibula are most often involved. Clubbing is obvious, and acroosteolysis can occur. Ankylosis of joints, especially in the hands and feet, may trouble older patients. The principal diagnostic challenge is secondary hypertrophic osteoarthropathy (pulmonary or otherwise), which instead features a smooth, undulating periostitis.[4] In pachydermoperiostosis, periosteal proliferation is more exuberant, irregular, and often involves epiphyses.[4] Bone scintigraphy in either condition reveals symmetrical, diffuse, regular uptake along the cortical margins of long bones, especially in the legs, causing a "double stripe" sign.

Laboratory Findings. Histopathologic examination shows that the new periosteal tissue undergoes cancellous compaction, rendering it difficult to distinguish from the original cortex.[79] Trabecular osteopenia reflects quiescent bone formation. Mild cellular hyperplasia and thickening of subsynovial blood vessels occur near synovial membranes. Increased circulating levels of prostaglandin E2 may be detected.[80]

Cause and Pathogenesis. Pachydermoperiostosis is caused by mutations of the *HPGD* gene that encodes 15-hydroxyprostaglandin dehydrogenase, which is involved in prostaglandin degradation,[81] or *SLC02A1* that encodes solute carrier organic anion transporter 2A1, which is involved in prostaglandin transport.[1]

Treatment. There is no specific medical treatment for pachydermoperiostosis. Painful synovial effusions may respond to nonsteroidal antiinflammatory drugs,[81] and myelofibrosis to prednisolone.[82] Contractures or neurovascular compression may require surgical intervention.

KEY POINTS

- Like the osteopetroses, most other heritable dense bone disorders can now be recognized by mutation analysis.
- The endosteal hyperostoses (sclerosteosis, van Buchem disease, LRP5 and 6 activation) are informative osteoblast-mediated (anabolic) bone disorders, including for pharmacologic treatment of osteoporosis.

OSTEOGENESIS IMPERFECTA AND HERITABLE OSTEOPOROSES

Osteogenesis imperfecta (OI) is increasingly a generic term for heritable "brittle bone disease."[83-85] The nosology for OI devised by Sillence and colleagues in 1979,[86] according to the principal features and the apparent inheritance pattern, was useful for prognostication and recurrence risk counseling. Then, collagen protein and later DNA-based findings focused on defective type 1 collagen. Germline mosaicism with autosomal dominant inheritance explained the especially severe type 2 form. Now, the clinical heterogeneity of classic OI is explained by many mutations throughout the two large genes that encode the pro-α_1 and pro-α_2 chains that combine to form the type 1 collagen heterotrimer.[1] Quantitative, and often qualitative, abnormalities compromise this most abundant protein in bone.[2] More recently, the genetic bases for especially rare forms of "OI," some no longer disrupting type 1 collagen, have been revealed.[83-85] Nevertheless, OI remains a heritable osteoporosis that causes fractures and skeletal deformity. Understandably, the severity of OI is extremely broad-ranging and spans neonatal death to asymptomatic mutation carriers.

Clinical Presentation. The differential diagnosis for OI in infants and children includes idiopathic juvenile osteoporosis, congenital indifference to pain, child abuse, homocystinuria, and a variety of other disorders. Classic OI has many typical features for diagnosis found in the medical history, physical examination, and radiographic findings. A positive family history is especially helpful, as many patients represent sporadic disease from a new mutation. The severity of this OI is often variable within families. Type 1 collagen is abundant not only in bone, but also in teeth, skin, ligaments, and sclerae, thereby explaining dentinogenesis imperfecta and abnormalities of other tissues that contain this fibrillar protein. Affected individuals can manifest ligamentous laxity, with joint hypermobility, diaphoresis, bruising, fragile and discolored teeth, and hearing loss (in ~50% of those patients <30 years and in nearly all who are older).[87] Deafness typically has conductive or mixed, but sometimes sensorineural, pathogenesis.[87] Scleral color can be blue or gray and subtle or striking. In severe classic OI, there is often a disproportionately large head, triangular face, high-pitched voice, short stature, scoliosis, herniae, and chest deformity. Mitral valve "clicks" are not uncommon, but cardiac disease is unusual. Intelligence is typically normal.

Type 1 OI features bluish sclerae (especially during childhood), relatively mild osteopenia with infrequent fractures (deformity is uncommon or slight), and deafness that manifests during early adult life.[86] Older women with type 1 OI can be mistaken as having postmenopausal osteoporosis. Subclassification into 1-A and 1-B is based on absence or rarely presence, respectively, of dentinogenesis imperfecta. Approximately one-third of type 1 patients represent new type 1 collagen mutations.

Type 2 OI causes prematurity, small size for gestational age, markedly soft skull, short and bowed limbs, numerous fractures, and a small thorax leading to death within the first weeks of life because of respiratory complications.[87]

Type 3 OI features recurrent fractures, including of long bone growth plates, leading to progressive skeletal deformity and short stature during childhood. Dentinogenesis imperfecta is common. Thoracic distortion predisposes to pneumonia.[86]

Type 4 OI features sclerae that appear normal, but with skeletal fractures and deformity, dental disease, and hearing loss.[86]

Now, especially rare autosomal recessive, autosomal dominant, and X-linked "OI"[83-85,88] includes severe forms because of defective enzymatic cross-linking of type 1 collagen.[89] The other disorders can be considered familial osteoporoses.

Radiographic Features. Radiographic findings in severe OI include generalized osteopenia, modeling defects featuring gracile long bones because of impaired periosteal bone formation, perhaps from weakness or non–weight-bearing, and deformities from recurrent fractures. Some severely affected infants have micromelia with wide major long bones. Recurrent fractures can deform vertebrae. Wormian bones in the skull, of significant number and size, are common but not pathognomonic.[90] Platybasia that can progress to basilar impression and excessive pneumatization of the frontal and mastoid sinuses are common with severe disease.[90] Appendicular abnormalities may worsen markedly during growth, a characteristic of "progressively deforming" type 3 OI. Here, "popcorn calcifications" within metaphyses, likely from traumatic fragmentation of growth-plate cartilage, appear during childhood in major long bones,[91] compromising their growth and contributing to short stature. They resolve when endochondral cartilage fully mineralizes and is replaced by bone at skeletal maturity. Fractures in OI often heal normally. Occasionally, hypertrophic callus, one of the hallmarks of type 5 OI because of a heterozygous mutation of the 5′-UTR of *IFITM5*, is mistaken for skeletal malignancy.

Osteoarthritis is frequent in ambulatory adults when there is bone deformity.

Laboratory Findings. Routine assessments of mineral metabolism are typically normal in OI, except hypercalciuria commonly occurs in severely affected children,[92] and nephrolithiasis seems prevalent during adult life. Elevations of markers of bone turnover characterize severe OI.

Bone histology usually reflects the abnormal skeletal matrix, especially in severely affected patients. Polarized-light microscopy often shows abundant disorganized woven bone, or thin collagen bundles in lamellar osseous tissue. Numerous osteocytes in cortical bone of some patients[93] could signify decreased bone produced by individual osteoblasts, yet many that are active. Hence, skeletal turnover can be rapid.[94]

Cause and Pathogenesis. The large size and complex nature of type 1 collagen is such that many and various heterozygous mutations are found within the genes that encode either pro-α_1 or pro-α_2 type 1 collagen.[1] The newer forms of OI reflect a considerable variety of causal genes.[83-85] A hallmark of classic OI is the paucity of often defective type 1 collagen synthesized by skin fibroblasts in culture.

Treatment. Support groups (e.g., the Osteogenesis Imperfecta Foundation in the United States) are important sources of comfort and lay-language information for OI patients and their families.

Genetic counseling for OI increasingly involves gene mutation analysis available in "OI panels" at commercial laboratories. Sporadic cases can reflect germline mosaicism for new dominant mutations in the genes that encode type 1 collagen. The recurrence risk for severe type 2 OI is 5% to 10%.[96] Some mildly affected individuals are mosaic, passing on severe disease to their child.

Prenatal detection of severe OI is possible by ultrasound examination at 14 to 18 weeks' gestation.[95] Now, mutation analysis is increasingly available for diagnosis.[83-85]

Treatment of OI often requires expert orthopedic, rehabilitative, and dental care.[96-97] Rodding of long bones and bracing of the lower limbs has enabled some severely affected children to walk. Stapes surgery has helped hearing loss. Bisphosphonate treatment has become commonplace for pediatric OI, but few trials have been placebo controlled.[98] Efficacy of bisphosphonates or teriparatide is less certain for affected adults. Increasing numbers of mouse models for OI are improving ways to test potential therapies. Clinical studies involve denosumab, parathyroid hormone analogs, and monoclonal antibodies to sclerostin and TGF-β1 (see ClinicalTrials.Gov).

KEY POINTS

- Mendelian osteoporoses have autosomal dominant osteogenesis imperfecta ("OI") as the paradigm "brittle bone disease."
- OI is typically caused by mutation of either of the two genes that encode the type I collagen heterotrimer. Some newer, autosomal recessive OIs feature gene defects that disrupt modification of this collagen.
- Heritable osteoporoses are increasingly identified by mutation analyses using panels of associated genes.
- Treatment may involve drugs or biologics used for acquired osteoporoses.

PAGET DISEASE OF BONE

Paget disease of bone (PDB) was once common in the United States (i.e., prevalence at least 1%, and perhaps 2%),[99] but now seems less so. The pathogenesis centers on focally accelerated skeletal remodeling in adults. Initially, a "wave" of osteoclast-mediated osteolysis moves slowly but relentlessly through a bone, followed by disorganized skeletal repair featuring bony expansion with hyperostosis and osteosclerosis. Pagetic bone is weak and can cause pain, fracture, and deformity. Skull involvement can lead to deafness of multifactorial pathogenesis. Rarely, pagetic lesions transform to osteosarcoma or chondrosarcoma.

Although the precise cause of all PDB remains uncertain, environmental factors acting upon a genetic predisposition (i.e., "diathesis") seem important. PDB prevalence in first-degree relatives is 12% to 40%, representing a 7-fold enhanced risk.[99] In fact, despite its classic focal appearance, PDB can manifest generalized acceleration in skeletal remodeling. Within PDB lesions, paramyxovirus infection could activate osteoclasts and their precursor cells. Here, the marrow microenvironment is especially osteoclastogenic and contains measles virus transcripts and proteins, perhaps explaining the inclusion bodies seen in PDB osteoclasts.[100]

Increasing evidence indicates that PDB is sometimes heritable. Characterization of familial expansile osteolysis (FEO), with its resemblance to PDB and obvious autosomal dominant inheritance,[101] rekindled earlier brief interest to identify a genetic basis for PDB (see later). Then, the rare syndrome called inclusion body myopathy with early-onset PDB and frontotemporal dementia was shown to be caused by autosomal dominant loss of function mutation of the gene that encodes valosin-containing protein.[102] PDB, particularly in French Canadians, was found to reflect heterozygous loss-of-function mutation in the *SQSTM1* gene that encodes sequestosome.[103] *SQSTM1* defects have been identified worldwide in large numbers of familial and some sporadic instances of PDB. Valosin-containing protein and SQSTM1 both seem to participate in ubiquination.[104] Now, predisposition to PDB is understood to be even more genetically heterogeneous.[105]

KEY POINTS

- Paget disease of bone (PDB), once "the second most common metabolic bone disease," seems to be waning in prevalence and severity worldwide.
- PDB diathesis ("predisposition") has an increasing number of associated genes.
- Paramyxovirus infection seems to underlie the characteristic focal bone lesions.
- Bone antiresorptive therapy, particularly the bisphosphonate zoledronic acid given intravenously, substantially controls active PDB.

DISORDERS OF INCREASED RANK/OPG/RANKL/NF-κB SIGNALING

Several other ultrarare but highly informative heritable disorders feature generalized acceleration of bone remodeling, specifically because of genetic defects within the receptor activator of nuclear factor-κB (RANK)/osteoprotegerin (OPG)/RANK ligand (RANKL)/NF-κB signaling pathway.[106]

Discovery of this regulatory system for osteoclast formation and action began with identification of new ligands and receptors in the tumor necrosis factor (TNF) superfamily, and then characterization of their knockout and transgenic mouse models.[107] Subsequently, clinical appreciation came from revelation of the genetic basis for FEO and several unique disease phenotypes from constitutive activation of RANK, and for juvenile Paget disease (JPD) owing to OPG deficiency.

In 2000, heterozygous gain-of-function 18-bp and 27-bp tandem duplications in the gene *TNFRSF11A* that encodes RANK were discovered to cause FEO and early-onset PDB,[101] respectively. In 2002, homozygous selective deletion of the *TNFRSF11B* gene that encodes OPG was found to cause JPD.[108] Then, in 2002 and 2014, similar 15-bp and 12-bp duplications in the gene encoding RANK explained expansile skeletal hyperphosphatasia[109] and panostotic expansile bone disease,[110] respectively.

Familial Expansile Osteolysis

FEO features deafness in childhood followed by generalized acceleration of skeletal remodeling and then focal lytic expansion of one or more major appendicular bones causing pain, fracture, deformity, and sometimes osteosarcoma in adult life.[106] Perhaps skeletal injury partly explains the focal bone lesions, which initially resemble the clinical, radiographic, and histopathologic appearance of PDB in its early osteolytic phase, starting near the end of a long bone and then slowly advancing. A tibia is most often involved. However, expanded bones eventually instead become shell-like and fat-filled, rather than exhibiting the hyperostosis and osteosclerosis of advanced PDB. These lesions are unresponsive to otherwise effective antiresorptive therapy given early on. Generalized osteopenia featuring a coarse trabecular pattern in adult life discloses the systemic nature of FEO bone disease. Conductive deafness presents in FEO as young as 4 years of age, but more commonly in the second decade, and ultimately becomes mixed-type. An especially remarkable finding in FEO is "idiopathic external resorption" that destroys teeth. The teeth have small pulp chambers and root canals, and fracture of adult dentition can also occur. Elevation in serum alkaline phosphatase activity and other biochemical markers of bone remodeling are partly because of the diffuse acceleration in skeletal turnover. Light microscopy of focal FEO bone lesions early on shows filigree-like trabeculae of woven bone, abundant osteoclasts and osteoblasts lining trabeculae, giant osteoclasts with bizarre shapes and numerous nuclei, and fibrous marrow. Electron microscopy reveals nuclear inclusions with ultrastructure like paramyxoviridae, as reported in PDB.[100] However, "mosaic bone," the hallmark of advanced PDB, is rare, perhaps explained by the extreme remodeling. Woven bone seems unable to mature or remodel into cortical bone. Perhaps focal loss of trabecular bone and instead fat-occupied medullary spaces in advanced FEO reflects mesenchymal stem cell differentiation into adipocytes. The molecular defect causing FEO was identified in 2000.[101] In three kindreds, an in-frame 18-bp tandem duplication was found within exon 1 of *TNFRSF11A* encoding RANK. Transfection studies suggested the RANK signal peptide extension trapped this receptor intracellularly, thereby increasing NF-κB activity.[101] Subsequent studies could not explain the enhanced osteoclastogenesis. Similar in-frame duplications in exon 1 encoding the signal peptide of RANK explain other disorders of constitutively enhanced RANK signaling.[109,110]

Osteoprotegerin Deficiency

JPD, also called idiopathic or hereditary hyperphosphatasia,[1] is usually diagnosed in infants or young children. A relatively mild form includes mental retardation.[111]

JPD affects the entire skeleton and causes bone pain, fracture, and deformity. Premature loss of teeth and deafness are typical. Radiographs show marked undertubulation of long bones with thin cortices (Fig. 59.6). Rapid skeletal remodeling, confirmed by

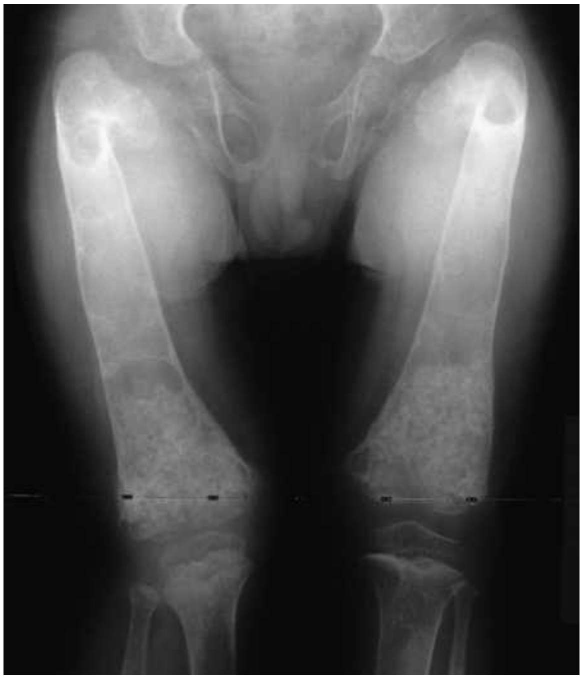

Fig. 59.6 Osteoprotegerin deficiency. The femurs of this boy with juvenile Paget disease are widened, with thin cortices and irregular ossifications. Marked angular deformity is present proximally.

histopathologic findings, leads to substantially elevated biochemical markers of bone turnover.[108,111] In fact, the mosaic pattern of bone characteristic of advanced PDB is not found in JPD or in the disorders of constitutive RANK activation.

Mild JPD features fewer fractures, less bony deformity, hyperostosis and osteosclerosis, as well as biochemical and histological evidence of generalized accelerated skeletal turnover,[108] which early on prompted objection to calling it a type of PDB. In 2002, OPG deficiency from homozygous absence of *TNFRSF11B* provided an obvious mechanism for the osteopathy.[108] OPG is normally on, or released into the marrow space by, preosteoblasts and osteoblasts, and acts as a decoy receptor for RANKL.[107] Thus, OPG deficiency enhances RANKL activity, which markedly accelerates osteoclastogenesis and bone turnover.[112]

TNFRSF11B knockout mice reveal a role for OPG also preventing vascular calcification.[112] Indeed, JPD patients can have striking histopathologic changes consistent with pseudoxanthoma elasticum,[113] including granular and coarse deposits of calcium in the membranes and intima of the muscular arteries and arterioles seen in all autopsy tissues from a young man with JPD.[113] Patients with JPD from OPG deficiency develop blindness from a retinopathy that seems to derive from microvascular calcification.[114]

Antiresorptive treatment using calcitonin or bisphosphonates has been beneficial for JPD,[103] but hypocalcemia may develop rapidly, especially with denosumab administration. Recombinant OPG was effective for two affected adult siblings.[115]

KEY POINTS

- Especially rare Mendelian disorders from gain- or loss-of-function mutations of the genes that encode receptor activator of NF-κB (RANK) or the decoy receptor osteoprotegerin (OPG) for RANK ligand (RANKL), respectively, illustrate the crucial role OPG/RANKL/RANK/NF-κB signaling has in humans for osteoclastogenesis and osteoclast action.
- All feature generalized acceleration of bone remodeling, some with focal lesions resembling those of Paget disease of bone, and respond to antiresorptive therapies.

WHAT IS OSTEOPOROSIS?

In 1993, a consensus conference defined osteoporosis as:

> *"… a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture."*[1]

The appearance of osteoporotic bone is illustrated in Fig. 60.1. This definition has stood the test of time fairly well. However, how the definition is operationalized in clinical practice has changed considerably since then. Initially, osteoporosis was diagnosed in those with spontaneous fractures or fractures after minimal trauma. The advent of bone densitometry resulted in osteoporosis being redefined in terms of an areal bone mineral density (BMD) more than 2.5 standard deviations below the mean value in the young normal population (i.e., a T-score < -2.5).[2] This approach was widely endorsed, but had the shortcoming of taking account of only one risk factor for fractures, namely bone density. It has subsequently become apparent that only approximately 20% of postmenopausal women with fractures have bone density T-scores less than –2.5.[3] This realization stimulated the development of fracture risk calculators,[4,5] which are now widely used, but with a variety of different intervention thresholds endorsed by various academic and funding bodies. Some groups, such as the National Osteoporosis Foundation (NOF) in the United States, recommend treatment based on several criteria, such as fracture history, bone density, or calculated risk of either hip or major osteoporotic fractures. Sometimes intervention thresholds are equated with diagnostic thresholds, but this is inconsistent. Because intervention thresholds are usually based on pharmacoeconomic analyses, they will vary not only with fracture risk, but also with cost of medication and willingness to pay, factors that would not usually impact on diagnostic criteria.

These problems of operational definition stem from the decision to regard osteoporosis as a disease. If, instead, it is regarded as a condition or process defined by the previous description, then the question of diagnosis does not arise. Rather, the physician's task is to assess fracture risk and make treatment recommendations based on that. This philosophical approach will be adopted in the present chapter.

KEY POINTS

- Osteoporosis is characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in fracture risk. Operational definitions vary and may be unhelpful. We suggest that physicians assess fracture risk and make treatment recommendations accordingly.

ORIGINS OF SKELETAL FRAGILITY

Several processes contribute to the increased fracture risk in osteoporosis. Most emphasis has focused on the reduction in the amount of bone (measured as bone mass or bone density), but there is also a deterioration in bone quality. Also, frailty contributes to increased numbers of falls with age, which also contribute to fracture risk. The many influences at play can be summarized by saying that the key requirements for healthy bone are: (1) a balanced diet to maintain normal lean and fat masses, (2) normal sex hormone levels, (3) safe physical activity, (4) normal levels of hormones that influence bone turnover, and (5) absence of chronic inflammatory disease.

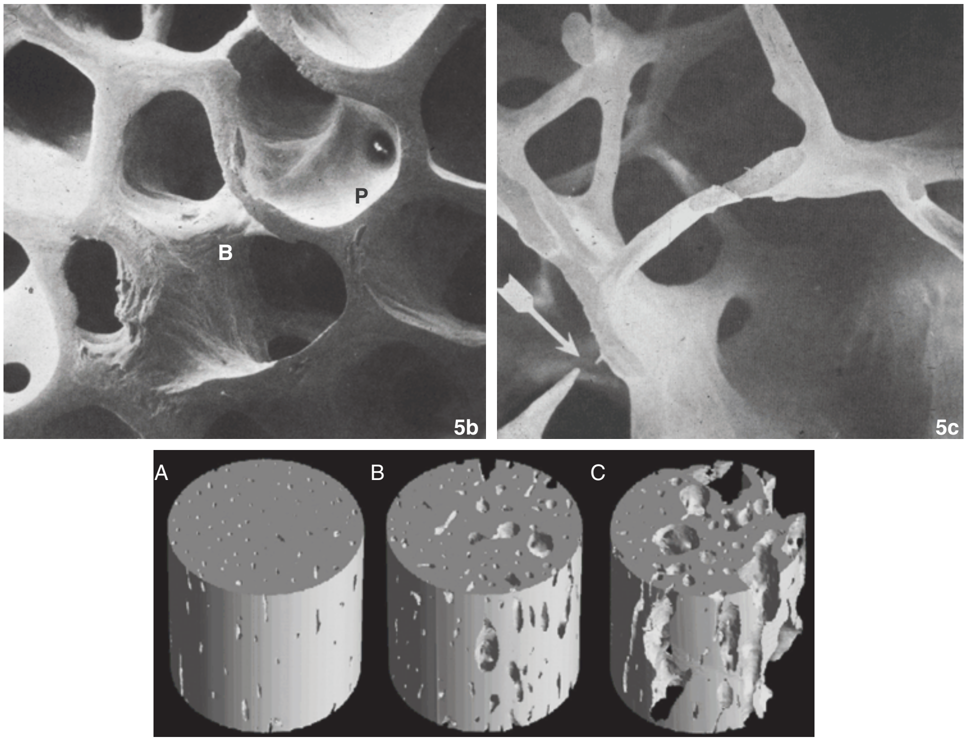

Fig. 60.1 **Normal and osteoporotic bone.** The upper panels show trabecular bone from the iliac crest in normal *(left)* and osteoporotic *(right)* individuals. The transition in architecture from exclusively plate-like structures to predominantly rod-like structures is noted, and results from trabecular perforation. Also note the osteoclast lacuna on the surface of the rod in the middle of the right-hand micrograph where perforation is imminent, and the wasting bone spicules in the lower left of the picture *(arrow)* where a rod has previously been perforated. The lower image demonstrates the normal loss of cortical bone in women aged 20, 61, and 87 years, respectively. P, trabecular plate; B, trabecular bar. (From Dempster DW, Shane E, Horbert W, et al. A simple method for correlative light and scanning electron microscopy of human iliac crest bone biopsies: qualitative observations in normal and osteoporotic subjects. *J Bone Mineral Res.* 1986;1:15–21; Cooper DML, Thomas CDL, Clement JG, et al. Age-dependent change in the 3D structure of cortical porosity at the human femoral midshaft. *Bone.* 2007;40:957–965; used with permission.)

Bone Density

At any age, bone density is determined by the amount of bone laid down during growth and the subsequent changes resulting from aging, drugs, or disease. Thus, factors that maximize bone mass gain during childhood and adolescence (e.g., global nutritional status, physical activity, timing of puberty, genes), those that maintain it during adulthood (normal gonadal function, nutrition, exercise), and those that delay or slow its loss during menopause and old age (timing of menopause, fat and lean masses, physical activity, vitamin D status) will reduce fracture risk. Throughout life, bone mass is also influenced by intercurrent illness, body weight, lifestyle factors such as exercise, and some medications, particularly glucocorticoids. Some of the common pathological and pharmacological contributors to osteoporosis are listed in Table 60.1.

Bone is a dynamic tissue and is constantly remodeled by the coordinated activities of osteoclasts (which remove old bone) and osteoblasts (which manufacture new collagen matrix, which is subsequently mineralized to produce bone). The activities of these cell types are coordinated by osteocytes, which sit in lacunae embedded in bone and have cell processes connecting adjacent osteocytes and communicating with the bone surface. This three-dimensional osteocyte network extends throughout bone and senses skeletal loading, as well as regulating the activities of both osteoblasts and osteoclasts. Osteocytes produce receptor activator of nuclear factor kappa-B ligand (RANKL; a protein that stimulates osteoclast development) and sclerostin (a protein that inhibits osteoblastic activity). Production of these factors is regulated by skeletal loading, circulating hormones, and local cytokines. At any time, approximately 20% of the trabecular bone surface is undergoing remodeling and, on average, the skeleton is replaced approximately every 10 years as a result of this process.

Bone is lost when bone resorption by osteoclasts exceeds the bone-forming activity of osteoblasts. In postmenopausal osteoporosis, the prime driver of bone loss is increased osteoclast activity resulting from the loss of the restraining effect of estrogen on the recruitment and activity of these cells. This results in losses of 20% to 30% of bone density at trabecular sites and 5% to 10% at cortical sites in the decade following menopause. The pivotal role of estrogen is demonstrated by the long-term maintenance of bone density with postmenopausal estrogen replacement.[6] Androgen status is also important in maintaining bone density in older men, and decline in free testosterone concentrations with age closely parallels bone loss in older men, which occurs at annual rates of 0.5% to 1%. Conversion of androgens to estrogens may be an important mechanism of their action on bone in men.[7] Osteoclast overactivity can also lead to perforation of trabeculae, resulting in deterioration in the microarchitecture of bone and leading to greater increases in fracture risk than the decline in bone density alone would predict.[8] It is likely that not all bone loss in older men and women is attributable to falling sex hormone levels. Multiple other aging processes result in cell senescence, including oxidative stress from increased mitochondrial production of reactive oxygen species,

telomere shortening, and impairment of DNA repair mechanisms. Bone cell senescence is associated with reduced osteoblast and osteocyte differentiation, as well as alterations in the stiffness and quality of the bone matrix. A more detailed account of cellular pathogenesis of bone loss is provided by Eastell et al.[9]

In contrast to postmenopausal bone loss, glucocorticoid treatment causes apoptosis of osteoblasts and osteocytes, resulting in inhibition of bone formation, although transient increases in bone resorption have also been reported early during treatment with these drugs.

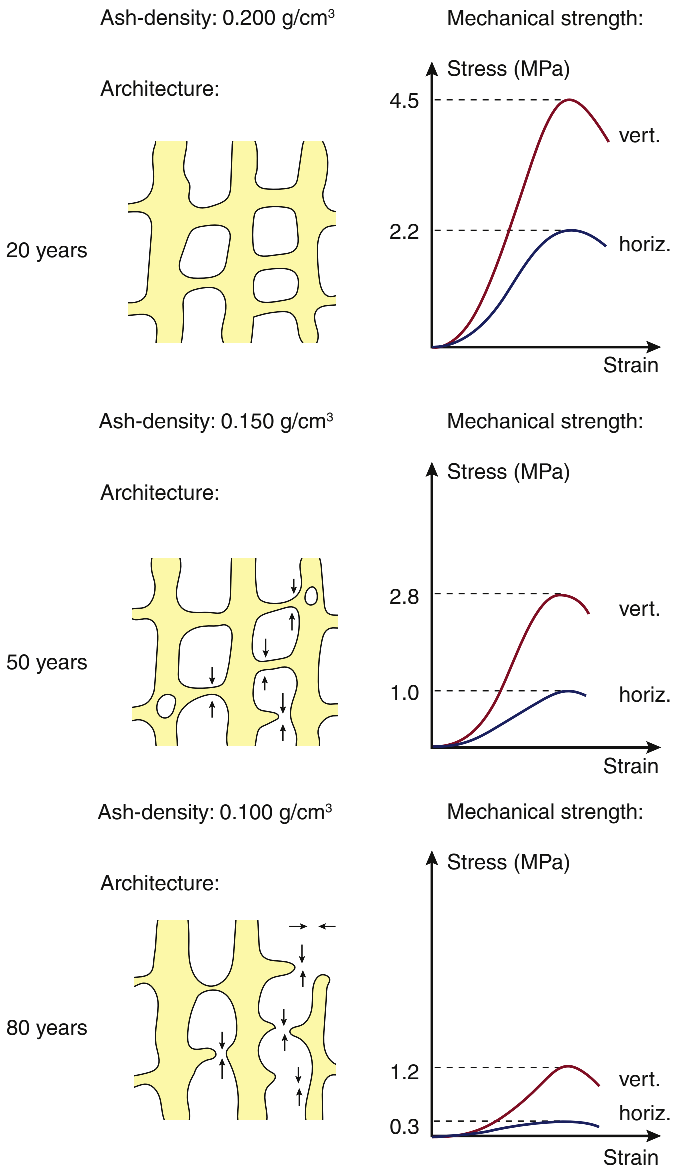

Fig. 60.2 Typical relationships among ash-density, architecture, and mechanical strength (vertical and horizontal) for vertebral trabecular bone obtained from three different age groups: 20 years, 50 years, and 80 years. (From Mosekilde L. Vertebral structure and strength in vivo and in vitro. *Calcif Tissue Int.* 1993;53:S121–S126; used with permission.)

Bone Quality

Epidemiological studies have made clear that bone density is not the only bone parameter that determines fracture risk. For instance, an 80-year-old woman with a femoral neck T-score of –3 is six times more likely to have a hip fracture than a 50-year-old woman with the same bone density, and a similar increase in fracture risk independent of bone density has been demonstrated in glucocorticoid users.[10] Both these observations indicate that there are elements of bone structure that are not captured with bone density measurement, and these are collectively referred to as bone quality. The components of bone quality are continuing to be defined, but include the material properties of both the protein matrix and the mineral phase of bone, as well as bone architecture. The integrity of collagen cross-linking, the state of cross-link isomerization, and content of advanced glycation end-products (resulting from nonenzymatic glycation of collagen) impact on skeletal strength. These aspects of bone matrix are influenced by the rate of bone turnover, which is regulated by sex hormones, cytokines, and genetic factors. Advanced glycation end-products are also influenced by ambient glucose concentrations and are increased in diabetes mellitus. This may contribute to the higher fracture risk than predicted by BMD in type 2 diabetes,[11] although in type 1 diabetes BMD is also reduced. Animal studies have suggested that the presence of microcracks in bone related to low turnover also reduce skeletal strength,[12] but a human study found that the compressive strength of vertebral trabecular bone was primarily determined by the amount of bone, not by cross-link profile, microdamage, or mineralization.[13] In pathological situations, such as severe vitamin D deficiency, bone mineralization can be substantially impaired, with a resultant decrease in bone strength.

The microarchitecture of bone impacts on its strength. As bone mass is lost, perforations occur in individual trabeculae (Fig. 60.1), resulting in a much greater decrease in bone strength than the decrease in mass would predict (Fig. 60.2). Consistent with this, loss of trabecular continuity is more frequently observed in patients with osteoporotic fractures than in controls. High bone turnover contributes to trabecular perforation by increasing the likelihood of resorption lacunae coinciding on opposite sides of a trabecula. Even if this proximity of lacunae does not lead to perforation, high turnover can increase trabecular fragility by causing critical trabecular narrowing where resorption lacunae are located close to one another on opposite sides of trabeculae. This may explain the independent association of bone turnover with fracture risk, which is probably also contributed to by the greater bone loss observed in high turnover states. In the cortex, increased osteoclast activity causes increased porosity (Fig. 60.1) and loss of strength, a process sometimes referred to as *trabecularization*.[14] In the first 15 years after menopause the greater surface area of trabecular bone results in its rate of loss being greater than in cortical bone. Subsequently, the increasing porosity of the cortex increases surface area in this compartment, whereas loss of trabecular elements reduces that surface area, so cortical loss exceeds that of trabecular bone.[14] Measures based on trabecular microarchitecture and cortical porosity appear to provide superior fracture prediction in older women than bone density measurement or the FRAX algorithm.[15]

Macroarchitecture is also important in determining skeletal fragility. One example of this is the positive association of hip axis length with hip fracture risk.[16] Increases in hip axis length and height (also a risk factor for fracture) probably have contributed to the secular increases in hip fracture risk as global nutrition has improved over the last 60 years. Macroarchitectural changes may partially offset the effects of age-related bone loss because long bones expand with age, which increases resistance to both bending and torsion. Other macroarchitectural parameters, such as outer diameter of the proximal femur and neck-shaft angle, have been associated with fracture risk in some populations.

Falls and Frailty

Epidemiology studies clearly demonstrate that the frequency of falls is closely related to the risk of fracture, and falls are the principal cause of skeletal trauma in the elderly. Propensity to fall is influenced by frailty, neuromuscular abnormalities, eyesight, sedative drugs, postural hypotension, and the safety of the home environment (presence of hazards such as loose carpets and electric cords, absence of safety devices such as handrails). Thus, understanding the etiology of frailty and of the resultant falls is a key part of understanding the pathogenesis of fractures in older people; but a detailed dissection of this is beyond the scope of the current chapter.

Nutrition

Nutrition has historically been regarded as a key contributor to the development of osteoporosis, but formal investigation provides only partial support for this hypothesis. Body weight is related to bone density and fracture risk throughout life[17] and is a key element in most fracture risk calculators. This is a dynamic relationship, with changes in weight directly impacting on BMD.

Interestingly, calcium intake has not being found to be useful in calculating fracture risk, and most recent studies do not demonstrate an effect of dietary calcium intake on adult bone density,[18] rates of bone loss in older people,[19] or fracture risk.[20] Earlier reports suggesting that calcium intake played an important role in bone health across the lifespan were substantially based on short-term *calcium* balance studies, which are contradicted by more recent studies of *bone* balance (using dual-energy x-ray absorptiometry [DXA]) over periods of up to 6 years.[19] Because bone mass and BMD are predictive of fracture, these recent results are more compelling. Consistent with these findings, calcium supplements do not impact on fracture risk, although they do have small effects on bone turnover and bone density.[20]

The vitamin D endocrine system is the principal regulator of intestinal calcium absorption. Its role in calcium homeostasis, together with the parathyroid glands, is to maintain normal concentrations of calcium in the extracellular fluid, thus permitting normal neuromuscular and cardiac function, blood coagulation, and other enzymatic activities. It is also critical that calcium concentrations do not exceed the normal range because this can result in deposition of calcium in soft tissues, with their resultant dysfunction. Vitamin D itself is without metabolic activity, but it is a substrate for production of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D. When supply of vitamin D is low enough to compromise production of 1,25-dihydroxyvitamin D, intestinal calcium absorption is impaired, and hypocalcemia and hypophosphatemia result. Hypocalcemia results in secondary hyperparathyroidism, which accelerates bone loss. Ultimately, bone mineralization is compromised, with resultant reduction in bone density and bone strength. Thus, severe vitamin D deficiency (25-hydroxyvitamin D <25 nmol/L) does have a profound effect on bone health, and such deficiency is observed in frail elderly individuals who seldom venture outside, in those who are habitually veiled, and in those with dark skin living at high latitude. In healthy community-dwelling adults with 25-hydroxyvitamin D greater than 25 nmol/L, vitamin D levels do not affect bone health, and supplements do not impact on bone density or fracture risk.[21-23]

Genetics

Genetic factors are important in bone health, with the heritability of bone density being 50% to 70%, and that for indices of bone architecture being 30% to 70%. Heritability of fracture risk is lower (20%–50%) and, at the hip, is highly age-dependent, dropping to near zero for first hip fracture after the age of 79 years.[24] These effects appear to be polygenic, with up to 200 different gene loci being implicated and accounting for up to 12% of the variation in BMD. Some loci are involved in pathways with a recognized role in bone (e.g., RANK and Wnt pathways), but many others are not, pointing to as yet undiscovered regulatory influences on bone. A much smaller number of loci have been shown to be associated with fracture.[25]

KEY POINTS

- Bone loss is a universal process in postmenopausal women and older men resulting from imbalance between bone formation and resorption. Bone architecture and the material properties of the bone matrix also change with age, as does frailty and risk of falling.

EPIDEMIOLOGY

Bone Mineral Density

Fig. 60.3 shows the distribution of BMD across the population, and the impact of age on it. BMD has a normal distribution throughout life, with young women by definition having a mean T-score of 0. By the age of 50 years, the mean T-score has diminished by only 0.38, but bone loss progresses more rapidly from that time through to the end of life. However, BMD remains normally distributed, with a standard deviation very similar to that in the young adult population. This demonstrates the universality of bone loss and strongly suggests that those who start at the upper end of the normal distribution in young adulthood will maintain that relative position subsequently, unless they suffer some specific disease or intervention that promotes bone loss (e.g., substantial weight loss, illness, long-term use of glucocorticoid drugs). BMD can also be presented as a Z-score, which is the number of standard deviations above or below the age-specific mean BMD.

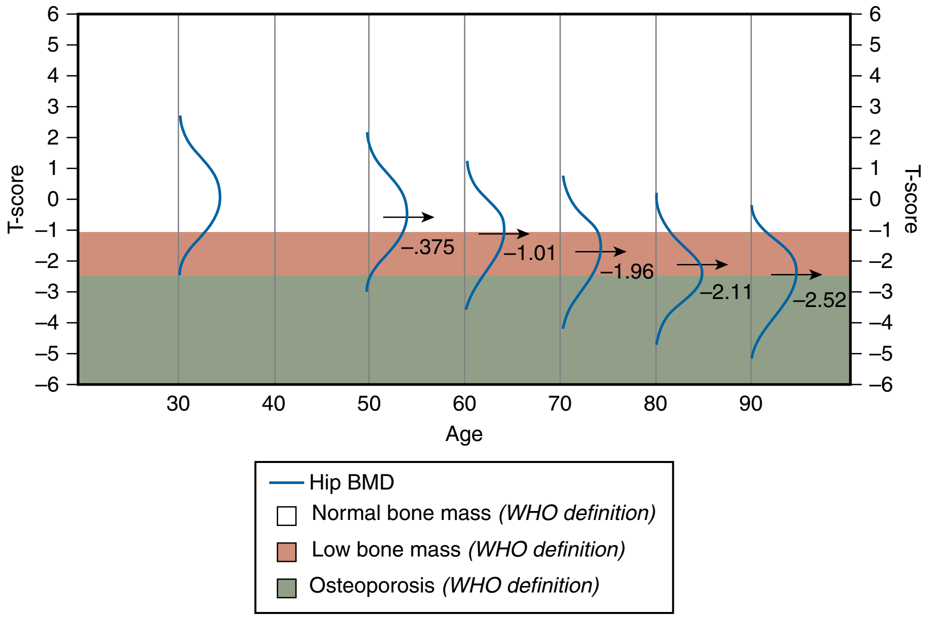

Fig. 60.3 The distributions of bone mineral density (*BMD*) and the decline with age for hip bone mineral density measured at the hip in White women in North America. *WHO*, World Health Organization. (From Cummings SR. Osteoporosis: Review of the evidence for prevention, diagnosis, and treatment and cost-effectiveness analysis — Status report. *Osteoporos Int.* 1998;8:S1–S85; used with permission.)

These data reinforce the suggestion that it is more appropriate to regard bone loss as part of the aging process rather than characterizing osteoporosis as being a "*disease*" because diseases usually affect individuals within a population rather than being experienced across the entire population. The universality of bone loss and the continuous distribution of bone density suggest that "*diagnosing*" osteoporosis is not an appropriate concept because any dichotomization of the population is necessarily arbitrary. Rather, bone density is one of a number of continuously distributed risk factors for fracture.

Fractures

The fall in bone density after the menopause is mirrored in a progressive rise in fracture numbers (Fig. 60.4). As a consequence, approximately one in five White women suffer a hip fracture between the age of 50 years and death, with similar incidences for clinical vertebral fractures and wrist fractures. Although these fractures are regarded as the "classical" osteoporotic fractures, they only represent approximately half of the total number of fractures that occur in this age group.[26] The remaining lifetime risk of any fracture in 60-year-olds is 56% for women and 29% for men.[27] Fracture prevalence is highest in Europe and North America and lowest in Africa, but hip fracture rates are increasing in much of the rest of the world, particularly in Asia.[28] This is contributed to by progressive increases in age-adjusted incidence rates and by a steady expansion in the numbers of individuals in the population over the age of 70 years.

Hip fractures are more common in winter, and usually result from falls, particularly falls to the side. There is an excess mortality at 1 year after hip fracture of approximately 20%, slightly higher in men than in women. About 50% of patients do not recover their former levels of mobility or ability to live independently after hip fracture, so this fracture has the highest costs in terms of loss of quality of life and need for ongoing care.

Vertebral fractures often occur after lifting rather than after falls. Only approximately one-third of vertebral deformities come to medical attention, hence the difference in rates of clinical versus radiographic vertebral fractures. Mortality is increased after vertebral fracture, to a lesser extent than after hip fracture, but the effect persists for greater than 5 years. Vertebral fractures result in height loss and kyphosis, with a resultant decrease in quality of life.

Risk Factors. Many observational studies have documented risk factors for fracture. As Fig. 60.4 indicates, age is a very important risk factor. BMD is also critical, with risk increasing by 1.5- to 2.0-fold for each standard deviation decrease in BMD.[29] Previous fracture increases risk almost 2-fold, with more recent fractures and clinical vertebral fractures carrying greater risk.[30] For this reason, fracture liaison services operate in many hospitals to ensure that those with fractures are offered interventions to prevent subsequent fractures. Almost one-third of women aged 55 to 90 years suffering a new fracture have had a previous fragility fracture,[30] highlighting the need for intervention following first fractures. Low body weight, family history, smoking, fall history, and markers of frailty are also important risk factors. Many risk factors are interdependent, so adjustment for other risk factors usually diminishes the predictive value of a given factor. This has led to the development of fracture risk calculators, which attempt to select the most parsimonious combination of predictive factors.

KEY POINTS

- Fracture risk climbs steeply with age and is also dependent on body weight, fracture history, falls, and bone density. The remaining lifetime risk of any fracture in White 60-year-olds is 56% for women and 29% for men but is lower in non-White persons. Increasing longevity is resulting in increasing total numbers of fractures.

ASSESSING PATIENTS AT RISK OF FRACTURE

Fracture Risk Assessment

The physician's goal in the evaluation and management of osteoporosis is to identify and offer treatment to those at the highest risk of fragility fracture. The cornerstone of this process is fracture risk assessment.

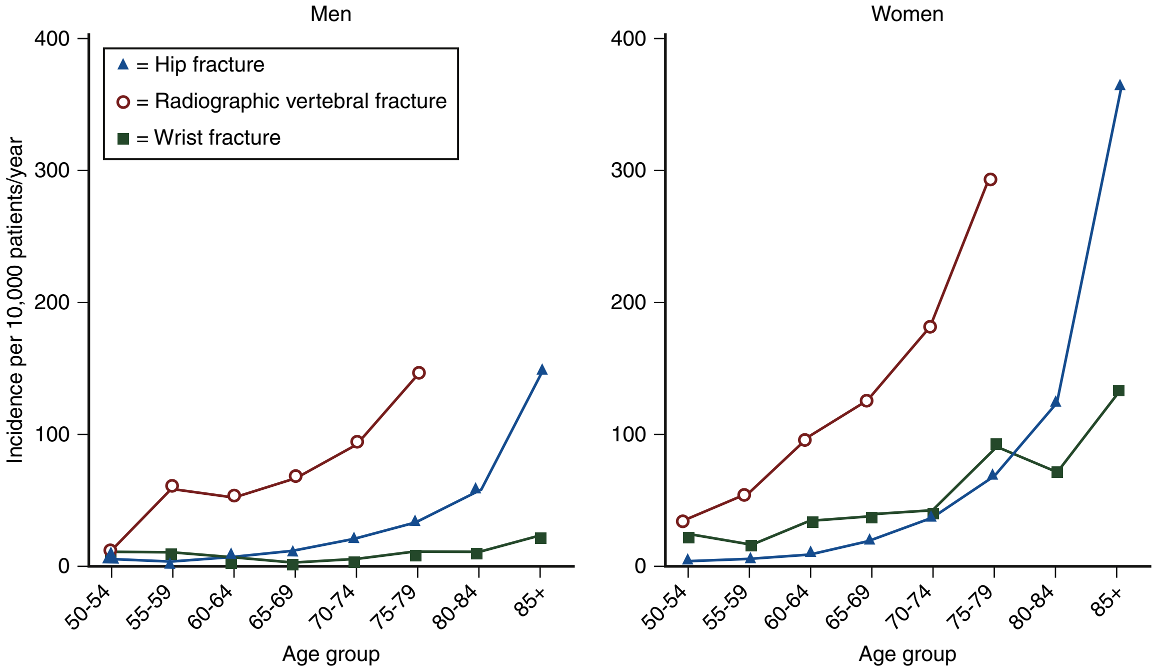

Fig. 60.4 **Fracture incidence by age and gender in England and Wales from 1988 to 1998.** (From van Staa TP, Dennison EM, Leufkens HG, et al. Epidemiology of fractures in England and Wales. *Bone.* 2001;9:517–522; used with permission.)

TABLE 60.2 Characteristics of Two Widely-Used Fracture Risk Calculators

	FRAX	Garvan
Clinical risk factors	Age (40–90 years) Sex Weight Height Previous fracture in adulthood (yes or no) Parent fractured hip Current smoking Glucocorticoid use Rheumatoid arthritis Secondary osteoporosis Alcohol Bone mineral density (optional) Country ± ethnicity	Age (50–96 years) Sex Fractures since age of 50 years (up to three) Falls over last 12 months (up to three) Bone mineral density or weight
Competing risk of death	Allowed for	Not allowed for
Fracture risk outputs	10-year risk of hip fracture or of a major osteoporotic fracture (i.e., hip, clinical spine, humerus, or forearm)	5- or 10-year risk of hip or any fragility fracture

Assessment of fracture risk involves the evaluation of a person's clinical risk factors for fracture (such as age, body mass index, prior low-trauma fracture) and the use of this information, often in conjunction with BMD results, to estimate the individual's absolute risk of sustaining a fragility fracture over a defined time period. The relationships between clinical risk factors, BMD, and fracture incidence are complex. As such, several fracture risk calculators have been developed to facilitate the assessment of fracture risk.[4,5] There are major differences in the variables that have been incorporated into the commonly used calculators, partly because different variables were available in the cohorts on which these calculators were based (Table 60.2). Both the FRAX and Garvan calculators can be used with or without entering BMD. For FRAX, inclusion of BMD makes surprisingly little difference to its predictive efficacy.[31]

In general, calculators produce similar estimates of risk in population studies but may generate disparate results for a given patient as a result of each focusing on different risk factors. Thus, FRAX underestimates risk (in comparison with Garvan) in those with falls or multiple fractures, but ethnicity differences in fracture risk are ignored by other calculators. In glucocorticoid-treated patients, FRAX does not take dosage into account, but a method has been described for revising FRAX estimates according to dose.[32] Similarly, FRAX risk estimates can be adjusted in patients with a considerably lower spine T-score than that at the femoral neck.[33] In general, the magnitude by which adjustment for high glucocorticoid doses and lumbar spine discordance change the initial FRAX estimate is small (on the order of 15%–20%), so the effects of adjustment are most clinically relevant when the initial estimate lies close to the treatment threshold. Fracture risk calculators were developed and validated for use in treatment-naïve individuals, but also appear to be reasonably accurate in those currently or previously receiving osteoporosis treatment.[34] FRAX has been validated in a number of populations, and country- and ethnicity-specific versions have been developed.

Risk assessment with FRAX can be done with or without a BMD result. In the United States, the NOF recommends BMD measurement as the entry point to fracture risk assessment, and, as such, BMD results are incorporated in fracture risk estimates.[35] Conversely, the UK National Osteoporosis Guidelines Group recommends initial fracture risk assessment without BMD, obtaining a BMD only if it has the potential to change management.[36]

When to Assess Fracture Risk. The age and other circumstances that are an indication for fracture risk assessment vary between countries. In Western countries, fracture risk assessment is typically recommended for all women aged 65 years or older[35,36] and in men older than 65 to 75 years. In women or men with clinical risk factors for fracture, risk is usually assessed in those over 50 years, although in high-risk contexts such as sustained glucocorticoid use, risk should be assessed in all age groups.

Bone Turnover Markers

Bone turnover markers are circulating factors that reflect either bone formation or resorption rates. Procollagen type I N-propeptide (PINP), a by-product of collagen synthesis, and the osteoblastic enzyme bone-specific alkaline phosphatase both reflect bone formation. Collagen degradation products can be measured in blood or urine as indices of bone resorption—serum C-terminal telopeptide of type 1 collagen (CTX) or urine N-terminal telopeptide of type 1 collagen. Higher bone turnover tends to be associated with higher fracture risk, but study results are inconsistent, and markers are not used in fracture risk assessment. They are increasingly used to monitor therapy, particularly oral bisphosphonates, and a CTX or PINP level in the lower half of the premenopausal reference range or a reduction of 40% to 50% from baseline indicates adequate delivery of drug to bone. CTX levels are markedly affected by time of day and meals, so are assessed during fasting in the morning.

Skeletal Imaging

DXA is the most widely used imaging modality for fracture risk assessment, but other radiographic techniques have been evaluated. Ultrasound of the heel is cheap and noninvasive but does not predict fracture as well as DXA does.[37] Assessment of BMD using quantitative computed tomography at the spine and femur has similar predictive ability to DXA for fragility fracture, but involves higher radiation exposure.[37] Therefore, performing quantitative computed tomography for the principal purpose of fracture risk assessment is not recommended, although opportunistic review of scans performed for other medical indications can identify individuals with low bone density who should be targeted for fracture risk assessment.[37] High-resolution peripheral quantitative computed tomography (HR-pQCT) has emerged as another promising tool for assessing both BMD and bone quality. This technique involves scanning of the radius and/or tibia and can provide a three-dimensional (volumetric) assessment of BMD. Scans obtained with HR-pQCT are of high enough resolution to permit differentiation between cortical and trabecular bone compartments and provide information about bone microarchitecture. Data obtained with HR-pQCT can also be used to estimate bone strength by finite element analysis. Although HR-pQCT can predict risk of fracture independent of DXA, its use is primarily limited to research at present, owing to the cost and scarcity of the required hardware and expertise.

Currently, the most clinically useful radiographic adjunct to DXA for estimation of fracture risk is trabecular bone score (TBS). TBS is a quantitative measure of the texture of a DXA image. It is determined using lumbar spine images and provides a reflection of trabecular bone quality. Incorporation of TBS has been shown to improve the ability of FRAX to predict fracture.

Other Investigations

In patients with markedly reduced BMD for their age (i.e., Z-score < –2), a search for underlying causes of bone loss should be undertaken. A clinical and medication history, together with physical examination, are important, as is consideration of the conditions listed in Table 60.1. Transiliac bone biopsy with tetracycline labeling is the gold standard for assessment of bone turnover and also provides detailed information about bone quality, but is seldom used, except in patients with severe unexplained osteoporosis or suspicion of osteomalacia.

KEY POINTS

- Fracture risk calculators are used to quantify risk, which guides the need for treatment. In patients with markedly reduced bone mineral density for their age (i.e., Z-score < –2), a search for underlying causes of bone loss should also be undertaken.

Interventions for Reduction of Fracture Risk. The most obvious approach to fracture prevention is to correct any risk factors for fracture that are present. These measures are grouped under the heading *Lifestyle*. The other broad group of interventions is the use of pharmaceuticals, including calcium and/or vitamin D supplements. Pharmaceutical agents for fracture prevention are classified as those inhibiting bone resorption and those that promote bone formation. Some, such as strontium, do not fit into either category, but this agent is now little used because of its marginal effect on nonvertebral fractures and its 60% increase in myocardial infarction, so will not be considered further here.

Lifestyle

Smoking cessation, moderation of alcohol intake, and treatment of the contributing diseases set out in Table 60.1 are obvious measures for reducing fracture risk. Discontinuation of the bone-damaging drugs listed in Table 60.1 is desirable from the point of view of skeletal health, but not always practical. However, dose minimization of glucocorticoids is a goal that should be actively pursued because the osteopenic effects of these drugs are dose related.

The skeleton is immediately responsive to the loads placed upon it, via the osteocyte stress-sensing network and the resultant secretion of regulatory factors by those cells, particularly sclerostin, which directly regulates bone formation. Thus, many studies have demonstrated that regular weight-bearing exercise increases bone density by a few percent, and this is maintained as long as the exercise is continued. Exercise is also of value in strengthening muscles, improving balance, and preventing falls. Metaanalyses have now demonstrated that exercise for falls prevention also results in reduced numbers of fractures.[38] In frail individuals who are falling frequently, pads (hip protectors) worn over the greater trochanters have been used. Some trials have shown major protective benefits to hip fracture from this intervention, although data are inconsistent, and compliance with the hip protectors is sometimes a problem.

Vitamin D. Vitamin D is often regarded as a nutrient, but unfortified diets contain very little vitamin D, and its circulating levels are mainly determined by sunshine exposure, habitual dress, latitude, and exercise. Adequate levels of vitamin D are required for the normal regulation of intestinal calcium absorption. Reduced vitamin D status results in secondary hyperparathyroidism leading to increased bone resorption; more severe vitamin D deficiency leads to low levels of calcium and phosphate in the extracellular fluid that are inadequate for bone mineralization. This is referred to as osteomalacia and results in reduced bone density, bone pain, and muscle weakness, plus, in children, the skeletal deformities of rickets. Vitamin D treatment in osteomalacia increases BMD by as much as 50%. This has led some to regard vitamin D as a potential bone anabolic agent, but the bulk of human data suggest that its role is restricted to the facilitation of intestinal calcium absorption and the prevention of secondary hyperparathyroidism.

Many studies have assessed the effects of vitamin D supplementation on BMD and fractures, but metaanalyses show no beneficial effect.[22] However, when vitamin D supplements are given to those with baseline 25-hydroxyvitamin D levels less than 30 nmol/L, clinically and statistically significant increases in BMD are demonstrable.[21,23] The study by Chapuy et al. carried out in elderly nursing home residents with marked vitamin D deficiency indicated that a combined supplement of calcium plus vitamin D did reduce fracture rates in these women, many of whom are likely to have had osteomalacia, based on their reported 25-hydroxyvitamin D levels.[39]

Routine measurement of vitamin D is not widely supported, because of its expense and the unreliability of some assays. In nursing homes, where patients are seldom outdoors, routine provision of a supplement is appropriate. Among the ambulant population, latitude, skin color, frequency of sunlight exposure, and habitual dress will allow most individuals at risk of severe vitamin D deficiency to be identified. Vitamin D supplements are usually given in a dose of 400 to 1000 IU/day (10–25 μg/day), and up to 2000 IU/day is regarded as safe. The long half-life of vitamin D has led to weekly, monthly, and annual dosing regimens delivering a similar average dose. Annual dosing is now discouraged, as the large bolus required increases the risk of fractures and falls. Daily doses of 4000 IU or more also increase falls and accelerate bone loss.[40,41] Vitamin D_2 and vitamin D_3 are often used interchangeably, but D_3 appears to have marginally greater efficacy, and D_2 is not detected by all 25-hydroxyvitamin D assays. Calcitriol or other 1-hydroxylated vitamin D metabolites have been assessed as treatments for osteoporosis but have not been consistently demonstrated to reduce fracture numbers, so are not used in most countries. Their use can result in hypercalcemia or hypercalciuria.

Diet. Many supplements have been advocated to increase bone health, but substantive data relating to most is lacking. Body weight and changes in weight directly impact on BMD. Fracture risk, particularly at the hip, climbs steeply when body mass index (BMI) is less than 20, although some limb fractures appear to be more common in obesity. Therefore, the optimal diet for bone health is one that has a balance of nutrients and maintains a healthy BMI.

Calcium. Consistent with the evidence cited above that calcium intake has little impact on bone health, introduction of calcium-rich foods or use of calcium supplements as a sole intervention has not been shown to influence fracture rates. Although the introduction of a calcium supplement does reduce bone turnover and lead to a BMD benefit of approximately 1% over the first year of use,[42] this BMD gain does not increase with longer-term use, accounting for the lack of effect of calcium supplements on fracture.[20] The United States Preventive Services Taskforce recommends against calcium or vitamin D supplementation for fracture prevention in noninstitutionalized postmenopausal women.[43]

Falls Prevention. The majority of fractures in older individuals occurs following falls—calculated fracture risk is doubled in those with falls in the previous 12 months. Therefore, fall prevention is an obvious way to reduce fracture numbers, and management of fallers involves both assessment to detect underlying disease causing falls (e.g., parkinsonism) and generic- and disease-specific interventions to reduce fall risk. Balance and strengthening exercises reduce falls and also appear to prevent fractures.[44] Optimization of vision (such as cataract removal and counseling regarding use of multifocal lenses), reduction or elimination of sedative drugs, prevention/treatment of postural hypotension, and provision of a safe home environment (including the provision of handrails and removal of falls hazards) are effective as part of multicomponent intervention programs. Vitamin D has been advocated for fall prevention, but evidence for its efficacy is inconsistent,[22] possibly because many studies have been carried out in populations not meeting current criteria for vitamin D deficiency.

Antiresorptive Medications

Because increased bone resorption is the principal mechanism of bone loss following menopause and in inflammatory conditions, inhibition of osteoclast activity is an obvious strategy for bone preservation. These were the earliest interventions used, in the form of calcium supplements (which reduce bone turnover by ~20%), calcitonin, and estrogen therapy in postmenopausal women. From the 1980s, bisphosphonates have been used in osteoporosis and remain the most widely used agents, being joined more recently by denosumab (Table 60.3). Calcitonin is now little used because of lack of consistent evidence for fracture prevention. A new class of antiresorptive drugs, the cathepsin K inhibitors, have excellent antifracture efficacy, but concerns regarding cardiovascular safety have caused odanacatib not to progress to the marketplace.

Bisphosphonates. The bisphosphonate nucleus consists of two phosphate groups linked through a central carbon atom. This P-C-P bond is stable in biological fluids, and there is effectively no metabolism of bisphosphonates in humans. The cluster of oxygen atoms in the bisphosphonate nucleus gives it a strong negative charge, which results in these molecules binding very tightly to the positively charged surface of bone. Thus, bisphosphonate in the circulation is rapidly taken up by bone, where it remains bound for years. When osteoclasts resorb bone coated by an aminobisphosphonate, they ingest the accompanying bisphosphonate, which then inhibits an enzyme, farnesyl pyrophosphate synthase, in the pathway leading to cholesterol synthesis (the mevalonate pathway). Blockade of this pathway results in cytoskeletal dysfunction and, ultimately, cell death. Non–nitrogen-containing bisphosphonates have other cellular targets, but these first-generation drugs are now little used in the treatment of osteoporosis. The specificity of the bisphosphonates for the skeleton arises from their avid uptake onto bone surfaces, the rapid excretion of the balance of the dose unaltered in the urine, and the fact that cells other than osteoclasts do not resorb bone.

Efficacy. Bisphosphonate treatment is accompanied by increases in BMD, as illustrated in Fig. 60.5. These tend to plateau after 3 to 4 years, and the extent of the increase varies between agents and between sites of BMD measurement. Because there is greater bone turnover in trabecular bone, sites rich in trabecular bone, such as the lumbar

TABLE 60.3 Principal Medications for Management of Osteoporosis

Medication	Dose	Indications	Dosing Instructions	Comments
Alendronate	70 mg/week PO 10 mg/day PO	Treatment of postmenopausal, male and glucocorticoid osteoporosis	Take fasting with a glass of water while sitting or standing. Remain upright and fasting for 30 minutes	
	35 mg/week PO 5 mg/day PO	Prevention of postmenopausal osteoporosis		
Risedronate	5 mg/day, 35 mg/week, 75 mg ×2 per month, 150 mg/month, all PO	Treatment or prevention of postmenopausal osteoporosis; treatment of male and glucocorticoid osteoporosis		
Ibandronate	150 mg/month PO	Treatment or prevention of postmenopausal osteoporosis	As above, but remain upright and fasting for 60 minutes	
	3 mg/3 months IV	Treatment of postmenopausal osteoporosis	Inject over 15–30 seconds	
Zoledronate or zoledronic acid	5 mg/year IV	Treatment of postmenopausal, male, and glucocorticoid osteoporosis, fracture prevention after hip fracture	IV infusion in 100 mL over at least 15 minutes	
	5 mg every 2 years	Prevention of postmenopausal osteoporosis		
Raloxifene	60 mg/day PO	Prevention and treatment of postmenopausal osteoporosis		
Denosumab	60 mg every 6 months SC	Treatment of postmenopausal, male, and glucocorticoid osteoporosis patients at high fracture risk		
Teriparatide	20 µg/day SC for 18–24 months	Treatment of postmenopausal, male, and glucocorticoid osteoporosis patients at high fracture risk	Follow with antiresorptive agent	FDA recommends considering >2 years of cumulative use during a patient's lifetime only if fracture risk remains high
Abaloparatide	80 µg/day SC for 18–24 months	Treatment of postmenopausal osteoporosis patients at high fracture risk	Inject into the periumbilical region. Administer initial doses where the patient can lie down if orthostatic hypotension occurs. Follow with antiresorptive agent	See above. Declined registration in Europe
Romosozumab	210 mg/month SC for 12 months	Treatment of postmenopausal osteoporosis at high fracture risk or patients who have failed or are intolerant to other available osteoporosis therapy	Follow with antiresorptive agent	

IV, Intravenously; *PO*, by mouth; *SC*, subcutaneously; *FDA*, US Food and Drug Administration.

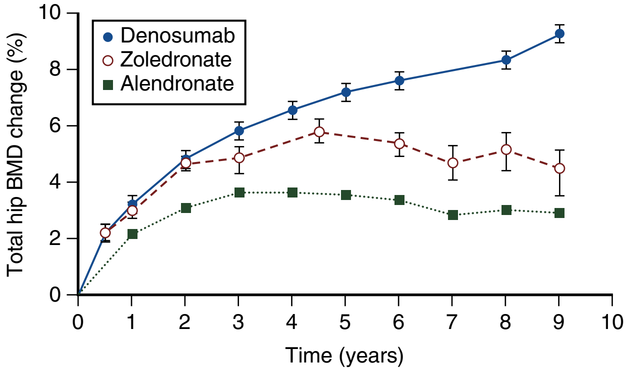

Fig. 60.5 **Long-term effects of osteoporosis treatments on total hip bone mineral density (*BMD*).** Data derived from the FLEX trial (alendronate, 5–10 mg per day), the HORIZON trial (zoledronate, 5 mg per year), and the FREEDOM trial (denosumab, 60 mg subcutaneous injection every 6 months). As data are derived from separate studies, formal comparisons between changes in BMD have not been made. (Modified from Reid IR. Short-term and long-term effects of osteoporosis therapies. *Nature Rev Endocrinol.* 2015;11:418–428; used with permission.)

spine, show greater BMD responses than more cortical sites, such as the mid-forearm and femoral neck. Despite differences between agents in antiresorptive potency, most of the aminobisphosphonates produce similar reductions in fractures, as demonstrated in Fig. 60.6. Although these drugs are very effective in reducing vertebral fractures (by as much as 70% with zoledronate), the reduction in total fracture numbers is a more modest 20% to 30%.

The prolonged residence time of bisphosphonates in bone raises the question of for how long these drugs need to be administered. Potential safety concerns with long-term continuous administration make this an important issue. Two studies have attempted to address the question of optimal duration of therapy for fracture prevention. In the FLEX study, women already on alendronate for 5 years were randomized to continue at their existing dose (10 mg/day), to continue at half that dose, or to cross over to placebo. Both groups continuing on alendronate maintained hip bone density, whereas those randomized to placebo tended to return to baseline BMD levels over the 5-year study. Rates of nonvertebral fractures were similar in all groups, but *post hoc* analyses indicated that, in those with a femoral neck BMD T-score less than −2.5 at the time they entered FLEX, continuation of

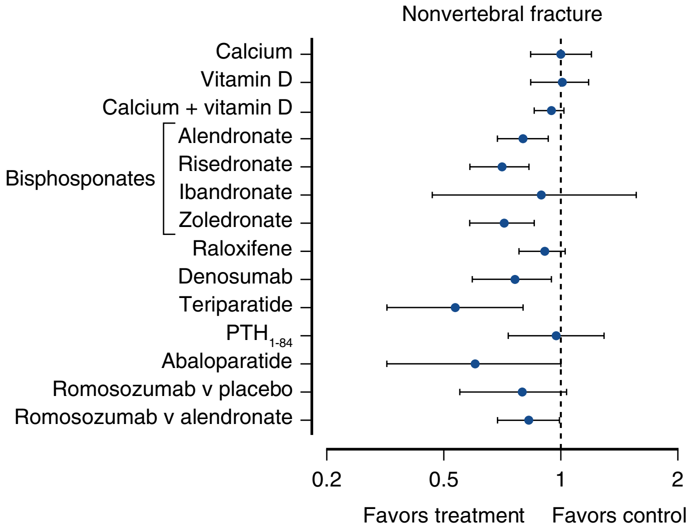

Fig. 60.6 Efficacy of treatments for the prevention of nonvertebral fractures. Abaloparatide data (hazard ratios) are at 18 months from Miller et al.[71] Romosozumab versus placebo data (hazard ratios) are at 12 months from Cosman et al.,[77] and romosozumab versus alendronate (hazard ratios) are at 24 months from Saag et al.[78] Parathyroid hormone (1–84) (*PTH1–84*) results are relative risks. Other results are odds ratios from the network metaanalysis of Murad et al.[82] Results are shown ± 95% confidence interval. (Modified from Reid IR. Short-term and long-term effects of osteoporosis therapies. *Nature Rev Endocrinol.* 2015;11:418–428; used with permission.)

alendronate reduced nonvertebral fractures by 50%.[45] Clinical vertebral fractures were also reduced by approximately one half in the alendronate groups compared with placebo. A similar study (to 9 years) was carried out in the phase III trial program for zoledronate, although it had only limited power to assess effects on fractures.[46] There was a partial loss of vertebral fracture efficacy if zoledronate was discontinued at year 3 (versus year 6), particularly in women with femoral neck T-score less than –2.5 at year 3. Bone loss in those discontinuing treatment at 6 years was less than 1% in the following 3 years, and there was no evidence of additional benefit with 9 years of therapy.

Common Side Effects. The most common side effect of oral bisphosphonates is upper *gastrointestinal irritation,* seen in 20% to 30% of users. Accordingly, patients are advised to remain upright for 30 minutes after ingesting bisphosphonates to minimize the risk of esophageal reflux. Oral bisphosphonates are contraindicated in those with active upper gastrointestinal disease. With intravenous aminobisphosphonates, the most common side effect is the *acute phase response*, comprised of fever, musculoskeletal pain, and malaise, frequently referred to as a “flu-like illness.” It can result in inflammation in almost any tissue, including the gastrointestinal system, the upper respiratory tract, and the eye.[47] With zoledronate, symptoms occur in 30% to 40% of patients in the week after their first dose and fade over a few days. Symptoms are only severe in 2% to 3% of those treated and decrease in frequency and severity after subsequent infusions. They are less frequent in those who have had oral aminobisphosphonates previously. Symptom frequency and severity are reduced by approximately half with either paracetamol/acetaminophen or a nonsteroidal antiinflammatory drug. Eye inflammation, typically uveitis, occurs in 1% of bisphosphonate-naïve subjects and is rapidly responsive to topical corticosteroids. It does not preclude further treatment with intravenous bisphosphonates, because, like other aspevects of the acute phase response, it does not necessarily recur with subsequent dosing.

Potent antiresorptive drugs sometimes cause *hypocalcemia* if administered to those with marked vitamin D deficiency (e.g., 25-hydroxyvitamin D <25 nmol/L). Vitamin D supplements should be provided to those judged clinically to be at risk of deficiency. Zoledronate is *nephrotoxic* in those with preexisting renal dysfunction and should not be administered when estimated glomerular filtration rate is less than 30 to 35 mL/minute. The use of a 1-mg or 2.5-mg dose of zoledronate, together with longer infusion times, could theoretically decrease renal toxicity in patients with marginal renal function.

In addition to these well-recognized side-effects, other safety concerns have arisen since bisphosphonates came into use. An increase in cases of atrial fibrillation was found in one phase III zoledronate study, but not in other major studies with this drug, nor with the other bisphosphonates. A small case series of carcinoma of the esophagus in oral bisphosphonate users was published, but other studies did not confirm this as a problem. The principal concerns that remain are osteonecrosis of the jaw (ONJ) and atypical femoral fractures.

Osteonecrosis of the Jaw. ONJ is defined as the presence of exposed bone in the mouth that fails to heal after appropriate therapy over a period of 6 to 8 weeks.[48] It usually develops following an invasive dental procedure, such as a tooth extraction, and the pathology is characterized by dead bone with overlying microbial biofilms that are very resistant to antimicrobial therapy. It was first described in the early 2000s in cancer patients receiving monthly infusions of pamidronate or zoledronate but is also clearly an issue in cancer patients receiving monthly denosumab injections, indicating that the development of ONJ is the result of potent suppression of bone resorption and is not specific to bisphosphonates. Whether ONJ is increased to a clinically significant extent in patients using antiresorptive drugs for osteoporosis treatment remains contentious. No cases were reported from the risedronate and alendronate development programs, but there was no awareness of ONJ as a clinical entity at that time. Postmarketing reports have suggested that the incidence of ONJ in patients receiving these drugs for osteoporosis is less than 2/100,000 patient-years. During the zoledronate phase III program, there was prospective adjudication of all potential cases, finding one case in each of the zoledronate and placebo groups (12,000 patient-years per group) and one during 1914 patients-years of observation in the study extensions. Studies of large databases have followed.[49] Although they clearly show that ONJ occurs in osteoporosis patients treated with antiresorptive drugs, they also demonstrate similar lesions at a similar frequency in osteoporosis patients not receiving these therapies. Case series in osteoporotic patients indicate that these ONJ-like lesions are lower grade than those seen in cancer patients, and that they are more likely to heal. Thus, the reality of this problem remains open to debate, although concern regarding it in the minds of the public and physicians remains a significant barrier to the more widespread use of these medications. It is also a major concern for dentists undertaking invasive procedures, so it is best not to start patients on bisphosphonates if such intervention is planned. Similarly, some dentists may wish to withhold bisphosphonates before tooth extractions. The long half-life of the bisphosphonates means that this is unlikely to change bone turnover at the extraction site, but, equally, the patient is unlikely to come to significant harm from the bone point of view if the medication is withdrawn for several months. Therefore, ascertaining a patient's current dental health status is advisable when considering initiating bisphosphonate therapy.[48]

Atypical Femoral Fractures. In 2008, reports appeared from Singapore and then the United States of the occurrence of transverse fractures of the upper femoral shaft in patients treated with bisphosphonates. Although femoral shaft fractures have always represented a few percent of fractures in osteoporotic subjects, and their frequency has not changed since the introduction of bisphosphonates to clinical practice, fractures with a specific radiologic appearance do seem to be more common in patients receiving antiresorptive drugs. These atypical femoral fractures start as stress fractures of the lateral femoral cortex that may be associated with local cortical thickening and thigh pain, then can progress to a complete transverse fracture with minimal comminution. Fractures are bilateral in approximately one-quarter of cases and are not usually the result of major trauma. Such appearances are sometimes seen in those who have never received antiresorptive drugs, and they have also been reported in other bone diseases. Most cases have been associated with alendronate use, although this might just reflect the wide use of this drug. None were reported in a recent 6-year study of 1000 women greater than 65 years receiving zoledronate,[50] and none in the extensions to the zoledronate phase III trial. A recent large Californian study suggests that incidence in the first year of bisphosphonate use is 0.2 per 10,000 patient-years, rising to 2.5 in years 3 to 5 and to 13 beyond 8 years of treatment. Importantly, there is consistent evidence that the risk drops rapidly after drug discontinuation, by more than half in the first year and by greater than 80% at 3 years.[51] It is important to remain mindful of the comparative rarity of these fractures. For instance, in a recent study of osteopenic postmenopausal women over the age of 65 years,[50] 20% of those on placebo had fragility fractures during 6 years' follow-up, a fracture rate of 333 per 10,000 patient-years, two to three orders of magnitude greater than the incidence of atypical fractures in California. Because zoledronate reduced fracture rates by one-third, the potential benefits from bisphosphonate use in appropriate patients clearly dwarf the problems associated with atypical femoral fractures. However, patients who develop thigh pain while taking bisphosphonates (or denosumab) should have appropriate radiology to determine whether there is evidence of a stress fracture. If there is, then bisphosphonate withdrawal and management in consultation with an orthopedic surgeon are appropriate. Prevention of these fractures is now the principal reason for drug holidays when using bisphosphonates, as discussed below.

Denosumab.

Denosumab is a monoclonal antibody directed against the protein RANKL, a key regulator of osteoclast development that is produced mainly in osteocytes. Denosumab is given by subcutaneous injection and produces near total arrest of bone resorption within days of administration. Bone formation indices decline by more than 60% over the 3 months following drug initiation, and bone histomorphometry confirms profound reductions in bone turnover (both formation and resorption), with a median zero bone formation rate after 2 to 3 years of use. The duration of effect is dose-dependent,[52] and in the conventionally used osteoporosis dose (60 mg) there is a marked offset of suppression of bone resorption beyond 6 months postinjection, with some variation in timing between individuals. Thus, if a denosumab injection is missed, bone resorption rises rapidly over 1 to 3 months after the injection was due, reaching levels more than 50% above baseline at 6 months. This is accompanied by rapid bone loss, with BMD returning to baseline within a year of drug discontinuation. Thus, the pharmacology of denosumab is profoundly different from that of the bisphosphonates, and this must be borne in mind when using these drugs clinically.

Efficacy. As expected for such a potent antiresorptive agent, denosumab produces substantial increases in BMD, which continue over 10 years of use (Fig. 60.5). Its effects on fracture are shown in Fig. 60.6, where the profile at the end of the three-year phase III FREEDOM study was very similar to that found in the phase III trial of zoledronate.[53] Ongoing follow-up of the active group from FREEDOM demonstrated that reductions in both vertebral and nonvertebral fractures were maintained to 10 years.[54]

Safety. The FREEDOM study found an excess of *skin infections* in those randomized to denosumab, although this has not been confirmed in the FREEDOM extension study, nor with extensive clinical use of the drug. FREEDOM also suggested that mortality was reduced by approximately 20% ($P = .08$), although the mechanisms of this are unclear. There were no *atypical femoral fractures* nor cases of ONJ during the core FREEDOM study. During the 7-year extension, there were two atypical femoral fractures (0.8 per 10,000 participant-years) and 13 cases of ONJ (5.2 per 10,000 participant-years), with all 11 patients with follow-up showing resolution. These rates are similar to those with other antiresorptive drugs, such as zoledronate. Potent antiresorptive drugs cause *hypocalcemia* in patients with marked vitamin D deficiency. Hypocalcemia has also been reported with denosumab use in those with renal impairment. Data from the Amgen postmarketing database covering 1,252,566 patient-years of use found four atypical femoral fractures, 32 cases of ONJ (with resolution in one-third), eight cases of severe symptomatic hypocalcemia (seven of whom had chronic kidney disease), and five cases of anaphylaxis.[55] These findings indicate that denosumab is a well-tolerated pharmaceutical and do not point to detectable adverse consequences from the sustained profound inhibition of bone turnover that it produces.

At present, the occurrence of *rebound fractures* following denosumab discontinuation is in the principal safety concern with this drug, particularly because long-term compliance with all osteoporosis drugs is poor. Most evidence for this problem comes from case reports and series. However, the FREEDOM extension study demonstrates that 15% of women discontinuing denosumab experienced a vertebral fracture subsequently, and in two-thirds of these (i.e., 10% of discontinuing patients) fractures were multiple. As many as nine fractures in a single patient have been reported, suggesting the possibility of substantial long-term disability from this problem.

The approach to rebound fractures is multifaceted. Patients need to be made aware of this problem before starting denosumab. It should not be initiated in those who are not committed to its long-term use or who are unlikely to be able to have follow-up injections in a timely manner. At the time of initiation, the prescribing physician should have an exit strategy in mind and have identified a medication to which the patient could transition following drug discontinuation.

In most instances, this will be a bisphosphonate, although which bisphosphonate is best and whether standard doses are adequate remain uncertain. Patients using denosumab because bisphosphonates are contraindicated represent a particular problem because it is not clear to what they should transition. Transitioning to teriparatide results in significant bone loss so is not usually appropriate.

Estrogen and Selective Estrogen Receptor Modulators. The key role of reduced ovarian estrogen production in postmenopausal bone loss is discussed above, so it is not surprising that administration of estrogen maintains BMD and reduces fracture risk.[6] In the Women's Health Initiative, hip and spine fractures were each reduced by 34% and total fractures by 24%.[56] Because estrogen receptors are present in many tissues, estrogen effects are widespread. This was demonstrated in the Women's Health Initiative, where beneficial effects on fractures and colon cancer were counterbalanced by changes in cardiovascular, cerebrovascular, and venous thromboembolic events.[56] The effects of estrogen alone appear to be different from those of combined treatment with a progestin, and may vary with specific agents within each class. This complexity has reduced enthusiasm for estrogen in management of osteoporosis, although its efficacy is firmly established. However, in the small proportion of women who have an elevated fracture risk in the decade following the menopause, the balance of benefit versus risk with estrogen appears to be positive.[57]

The 1990s saw the emergence of a new class of drugs called selective estrogen receptor modulators (SERMs), which bind to the estrogen receptor, producing tissue-specific agonist or antagonist effects. Thus, it is theoretically possible to have an agent that will mimic the beneficial effects of estrogen (such as maintenance of BMD) yet avoid its adverse effects, such as the promotion of breast cancer. Raloxifene is a SERM that has been widely used in osteoporosis, although its effects on BMD are significantly less than those of estrogen,[58] and it reduces only vertebral, not nonvertebral, fractures.[59] It reduces breast cancer risk, but, like estrogen, it increases the risk of thromboembolic disease. Another SERM, bazedoxifene, has been marketed in combination with conjugated estrogens for management of menopausal symptoms. Although it increases BMD, its antifracture efficacy has not been established. Because the available SERMs lack evidence of efficacy against nonvertebral fractures, they have only a minor role in osteoporosis management.

Tibolone is a synthetic steroid with weak estrogenic, progestogenic, and androgenic activity, and it prevents vertebral and nonvertebral fractures.[60] There is inconsistent evidence of its effects on breast cancer, and it increases stroke risk. It is used in Europe for osteoporosis treatment and management of menopausal symptoms, but not in North America.

Anabolic Medications

Anabolic medications stimulate bone formation. This action offers the possibility of increasing bone mass and, possibly, restoring microarchitecture, whereas antiresorptive agents essentially preserve bone structures that are already present. Anabolic treatments may be particularly appropriate in those with a high fracture risk. Modified androgens (anabolic steroids) have been used in the past in this role, but their androgenic side effects have limited their use, and antifracture efficacy has not been established. Until recently, analogs of parathyroid hormone (PTH) were the only such agents available, acting predominantly via PTH type 1 receptors on osteoblasts and osteocytes. The field has broadened recently with the advent of abaloparatide, an analog of PTH-related peptide, and with the development of antisclerostin antibodies (Table 60.3).

Teriparatide. Until the 1980s, PTH was regarded as having a negative effect on bone, being the principal stimulator of bone resorption. Thus, in patients with primary hyperparathyroidism, management of osteoporosis was a reason for parathyroidectomy. However, it is now clear that PTH stimulates both bone formation and bone resorption, the balance between these being determined by the dosing regimen. Sustained high levels of PTH, as in primary hyperparathyroidism, result in greater stimulation of resorption, particularly in cortical bone, leading to bone loss. In contrast, daily pulses appear to be anabolic, particularly in axial trabecular bone. Intact PTH has 84 amino acids, although most of its biological activity appears to reside in its N-terminus. A variety of PTH analogs have been assessed in osteoporosis, but PTH(1–34), known as teriparatide, is the principal one in current use.

Efficacy. Teriparatide transiently increases the activation frequency of bone remodeling, followed by progressive increases in bone density over the 18 to 36 months, particularly in the spine.[61] In the first year of therapy, PTH has little beneficial effect on femoral neck BMD, although beyond 12 months more positive changes are observed.[61] In the radius, the conventional dose of teriparatide (20 μg) has no beneficial effect, and 40 μg/day accelerates bone loss. When compared directly with alendronate, teriparatide produces greater increases in spine BMD but is less effective than alendronate in the proximal femur during the first year of use.[61] However, teriparatide reduced numbers of vertebral fractures by two-thirds and nonvertebral fractures by one-third over a median treatment period of 21 months in the phase III trial.[62] Only nine hip fractures occurred in this trial, so this aspect of efficacy was not addressed, although a subsequent metaanalysis suggested that teriparatide does prevent hip fractures.[63] The VERO trial directly compared fracture prevention with teriparatide (20 μg/day) and risedronate (35 mg/week) in postmenopausal women with existing vertebral fractures.[64] Over 2 years, new vertebral fracture incidence was reduced by more than half and new nonvertebral fractures by approximately one-third in the teriparatide group compared with risedronate, although the latter difference was not statistically significant.

A Japanese study has assessed the efficacy of teriparatide given weekly (dose 56.5 μg) over 72 weeks. Vertebral fractures were reduced by 80%, but the relative risk of nonvertebral fracture was 0.98 (0.47, 2.07).[65] The efficacy of this regimen has not been assessed elsewhere. Teriparatide has BMD effects in men similar to those in women, although fracture prevention has not been rigorously studied. In glucocorticoid-induced osteoporosis, teriparatide produces larger BMD increases than alendronate and substantially reduces vertebral fracture risk.[66]

Because the actions of teriparatide on bone formation potentially complement those of antiresorptive agents, there has been interest in studying combination therapy. An early study combining PTH(1–84) with alendronate did not suggest much advantage from this approach, but subsequent trials of teriparatide plus zoledronate[67] and of teriparatide plus denosumab[68] have both suggested additivity of BMD effects, although fractures were not endpoints of these studies. However, clinical fractures (reported as adverse events) were less frequent in the combination therapy group compared with zoledronate alone ($P = .04$).

Treatment sequences have also been evaluated. Cosman et al. randomized osteoporotic women on alendronate to addition of or switching to teriparatide and found that continuation of the alendronate after starting teriparatide produced more positive changes in bone density than did a switch of therapy.[69] Transitioning from teriparatide to denosumab produces positive effects on bone density, but the reverse sequence is associated with initial bone loss, so is not recommended.[70] Because duration of therapy with teriparatide is restricted to 18 or 24 months in most jurisdictions, it is important to have a transition plan in mind when teriparatide is initiated, as its BMD effects wear off over 1 to 2 years after drug cessation. Transition to either a bisphosphonate or denosumab is the usual practice.

Another PTH analog, PTH(1–84), was assessed in a phase III trial. There were high dropout rates, and an equivocal reduction in vertebral fractures was found, but nonvertebral fracture rates were not changed. Thus, PTH(1–84) is now little used for osteoporosis treatment.

Safety. In the phase III study, the 20 μg/day dose was well tolerated, but the 40 μg/day dose was associated with nausea and headache.[62] Serum calcium levels 4 to 6 hours postinjection were above the normal range in 2% of the placebo group and in 11% of the 20 μg group, and dose reduction for this reason was required in 3% of this group. The frequency of hypercalciuria was not increased by teriparatide. In the study of weekly teriparatide injections, nausea, headache, and abdominal pain led to 19% of the teriparatide group stopping treatment, compared with 7% in the placebo group.[65] These studies did not find an increase in the frequency of arthralgia or other musculoskeletal symptoms in the active treatment groups, although this has been anecdotally reported as a problem in clinical practice.

The phase III teriparatide trial was stopped because rat studies found a high incidence of osteosarcoma after high doses of teriparatide over several years. This led to restrictions in the permissible duration of administration of PTH peptides to 18 to 24 months. However, a decade of clinical surveillance has not produced evidence that this is a problem in humans. This suggests that second courses of treatment with teriparatide may be safe, and there is evidence of BMD increases with retreatment. Teriparatide is contraindicated in those at increased risk of osteosarcoma (e.g., previous skeletal radiation and, possibly, Paget disease), in hypercalcemia, in metabolic bone disease other than osteoporosis, and in patients with skeletal malignancies or bone metastases.

Abaloparatide. Abaloparatide is an analog of human PTH-related peptide(1-34). Like teriparatide, it acts through the PTH1 receptor, stimulating bone turnover. Some studies suggest that it has a preferential effect on bone formation over resorption, but findings are inconsistent. Abaloparatide is available in the United States but has been declined approval in Europe because the decrease in nonvertebral fractures is of marginal significance, because data from two study centers were judged to be unreliable, and because of an increase in palpitations in the abaloparatide group.

Efficacy. In the phase 3 trial, 2463 osteoporotic postmenopausal women were randomized to 18 months' treatment with placebo, abaloparatide 80 μg/day, or to open-label teriparatide 20 μg/day.[71] Teriparatide tended to increase bone turnover markers (both formation and resorption) more than abaloparatide, and increases in BMD were greater with abaloparatide. Vertebral fracture risk compared with placebo was reduced by more than 80% by both interventions, but nonvertebral fracture was only significantly reduced in the abaloparatide group. Hypercalcemia was less common with abaloparatide (3.4%) than with teriparatide (6.4%). At 19 months, participants from both the abaloparatide and the placebo groups were switched to active treatment with alendronate and continued to 43 months.[72] Vertebral fracture rates remained suppressed by more than 80% during this extension. For nonvertebral fractures there was a 39% reduction in the abaloparatide/alendronate group compared with the placebo/alendronate group over the entire 43 months ($P = .04$).

Safety. Abaloparatide was generally well tolerated in the phase III trial, with complaints of nausea and headache, as with teriparatide. Palpitations were reported by 5% of abaloparatide participants, compared with 0.4% in the placebo group and 1.6% in those receiving teriparatide. Hypercalcemia occurred less frequently than in the teriparatide group (6.4% vs. 3.4%). As with teriparatide, rat toxicology studies demonstrated an increased risk of osteosarcoma. Therefore, the contraindications to use and the limitations on treatment duration that apply to teriparatide also apply to abaloparatide.

Antisclerostin Antibodies. Sclerostin is produced in osteocytes and is regulated by bone loading and by hormonal influences such as PTH. It is released at the bone surface via the osteocytic cell processes, where it acts as a potent inhibitor of Wnt signaling in osteoblasts, dramatically reducing bone formation. The Wnt pathway also stimulates secretion of osteoprotegerin, an osteoblast protein that reduces osteoclast formation and, thus, bone resorption. Thus, sclerostin is an attractive target for monoclonal antibodies. This potential has been fulfilled with the development of romosozumab, which acts as a potent stimulator of bone formation but also reduces bone resorption, resulting in accelerated fracture healing in rats.[73]

Efficacy. Single doses of romosozumab in humans have anabolic and antiresorptive effects on biochemical markers that persist for 1 to 2 months. The phase II study in postmenopausal women with low bone density showed dose-related effects on BMD, with increases in spine and hip BMD of up to 11.3% and 4.1%, respectively, at 1 year, substantially greater than was seen with teriparatide or alendronate in the same study.[74] BMD increases continued in the second study year to 15% and 7%, respectively. Crossover to placebo at 24 months resulted in loss over the subsequent year of more than half of the BMD gained, a deficit that was reversed with a further year of romosozumab in study year 4. Other participants were crossed over to denosumab in year 3 and showed continuing gradual BMD gain, which continued in year 4 with crossing back to romosozumab. Romosozumab was without effect on BMD at the distal third of the radius. The BMD changes were preceded by a 100% increase in PINP (a marker of bone formation) and a 30% decline in the bone resorption marker, C-telopeptide, in the first study month. Subsequently, these markers were close to baseline levels during the period when BMD was increasing most. A subsequent BMD study comparing romosozumab with teriparatide also demonstrated superiority of romosozumab.[75]

Bone histomorphometry in older women treated with romosozumab showed that trabecular and endosteal bone forming surfaces were increased 3- to 4-fold at 2 months, but that this was no longer evident at 12 months. Osteoclast numbers on these surfaces were reduced to near zero at both timepoints. As a result, trabecular bone volume was increased by approximately 50% at 12 months, mainly as a result of increased trabecular thickness. Cortical bone was little affected by romosozumab.[76]

There have been two phase III trials of romosozumab in postmenopausal women. The FRAME study enrolled 7180 postmenopausal women who had BMD T-scores of –2.5 to –3.5 at the total hip or femoral neck.[77] Patients were randomly assigned to receive romosozumab (210 mg) or placebo monthly for 12 months. Thereafter, patients in both groups received only denosumab (60 mg every 6 months) to month 36. At 12 months, romosozumab reduced the risk of new vertebral fractures by 73% ($P < .001$) and nonvertebral fractures by 25% ($P = .1$), with similar results at 24 months. Clinical fractures were reduced by 36% at 12 months and 27% at 3 years compared with the placebo/denosumab group.

The ARCH study enrolled 4093 postmenopausal women who had osteoporosis plus a fragility fracture and randomly assigned them to receive monthly romosozumab or weekly oral alendronate (70 mg) for

12 months, followed by open-label alendronate alone in both groups.[78] Over 24 months, new vertebral fractures were reduced by 48% ($P < .001$), nonvertebral fractures by 19% ($P = .04$), and hip fractures by 38% ($P = .02$) in the romosozumab-to-alendronate group compared with the placebo-to-alendronate group. Clinical fractures were significantly reduced by 28% at 1 year and by 27% at 3 years.

Safety. In the FRAME study, romosozumab was well tolerated, but one atypical femoral fracture and two cases of ONJ were observed in the romosozumab group. In ARCH, total adverse events and serious adverse events (including atypical femoral fractures and ONJ) were balanced between the two groups. However, during year 1 serious cardiovascular adverse events were observed more often with romosozumab than with alendronate (2.5% vs. 1.9%), an imbalance not seen in FRAME. The reason for the different cardiovascular profiles in these two studies is unclear, but it is possible that alendronate had a cardioprotective effect in ARCH, although this has not been clearly demonstrated in the many other trials using alendronate. As a result, in some jurisdictions romosozumab carries a warning regarding cardiac safety, and its use is discouraged in those with recent cardiovascular events.

KEY POINTS

- Correction of reversible risk factors is the first line of intervention. Antiresorptive drugs are the most commonly used drug treatments, with 1- to 2-year courses of anabolic agents used as adjunctive therapy in those at highest fracture risk.

TREATMENT DECISIONS

Whom to Treat

In the introduction to this chapter, reference was made to the progressive evolution of the definition of osteoporosis. A similar path has been followed in determining whom should receive treatment, and there is not yet consensus on this question. When osteoporosis was diagnosed from the presence of a low-trauma fracture, then this was also the indication for treatment. A similar course was followed when the diagnosis moved to a BMD T-score of less than –2.5. The advent of fracture risk calculators permitted treatment decisions to be based on pharmacoeconomic analyses, resulting in a 10-year hip fracture risk of 3% or a major osteoporotic fracture risk of 15% to 20% being proposed as thresholds. These determinations were made at a time when conventional therapies cost several hundred dollars annually. We now have a wide range of costs, with generic bisphosphonates available for only a few dollars annually in some countries, but injectable anabolic therapies costing tens of thousands of dollars in others. This means that the former are cost-effective in women with a hip fracture risk of only 1% over 10 years, but the latter are only cost-effective in those at very high fracture risk.

A recent analysis of 55,000 women aged over 40 years who were followed for more than 5 years in the Manitoba BMD registry compared the sensitivities and specificities of commonly used thresholds. Among women in their 60s at baseline, 3% to 30% met the criteria for intervention, but these criteria only identified the 6% to 44% of those who fractured during follow-up. Among women in their 70s, intervention thresholds were met in 15% to 56%, identifying 23% to 71% of those who subsequently fractured.[31] The more inclusive National Osteoporosis Foundation criteria identified a greater proportion of women as being at risk and showed greater sensitivity (although lower specificity) in identifying those who subsequently had fractures. These data highlight the shortcomings of the calculators currently available and indicate that a broad use of antifracture medications is necessary if a substantial reduction in total fracture numbers is to be achieved. The numbers needed to treat in the Manitoba study suggest that broader treatment strategies are likely to be cost-effective for inexpensive medications such as bisphosphonates. Similar conclusions come from the recent trials of screening strategies for osteoporosis.[79] Screening resulted in intervention in only 6% to 18% of participants, with no change in total fracture numbers resulting, although some fracture subtypes were reduced.

In conclusion, whom to treat remains uncertain. Of the various strategies proposed, the multifaceted proposals of the National Osteoporosis Foundation appear to be best in terms of their sensitivity for future fracture. However, a UK cost-effectiveness analysis (National Institute for Health and Care Excellence) suggests that an even more inclusive strategy of treating women with a 10-year hip fracture risk of more than 1% is justified for the use of generic bisphosphonates. In such low-risk groups, the possibility of side effects becomes a key factor in determining whether to recommend intervention. Patients' enthusiasm for intervention will vary widely and is not necessarily related to absolute fracture risk or to arbitrary treatment thresholds.

Selection of Treatment

An initial step in providing osteoporosis treatment is a consideration of the likelihood of vitamin D deficiency in that patient, and correction of that as required. If pharmaceutical intervention is justified, the first line will usually be a *bisphosphonate*, on the basis of their efficacy, safety, and low cost. The choice between oral and intravenous bisphosphonates is a pragmatic one based substantially on patient preference. Intravenous bisphosphonates require infusion facilities and carry the risk of an acute phase response. They are more expensive in some countries. Intravenous bisphosphonates should not be administered to patients with glomerular filtration rates less than 30 to 35 mL/min. However, their major advantage is the certainty that the active drug has been delivered to the bone surface, plus the infrequency of dosing, particularly with zoledronate, where dosing as little as every 5 years can maintain bone density in postmenopausal women.[80] Oral bisphosphonates carry the risk of upper gastrointestinal symptoms and require adherence to the correct dosing requirements (taken fasting with a glass of water, at least 30 minutes before other fluids or food, with the patient remaining upright during this period).

Denosumab is also used as a first-line antiresorptive therapy, although it is more expensive than most bisphosphonates. It has the convenience of subcutaneous administration and is without any postdose side effects. The principal caution in its use is the rebound increase in bone resorption that occurs if the 6-monthly injection is delayed or the drug is discontinued without transition to another agent. The occurrence of clusters of vertebral fractures in as many as 10% of discontinuing patients requires that an exit strategy is carefully considered, and discussed with the patient, *before* denosumab is initiated. Denosumab can be used in those with marked renal impairment, although hypocalcemia may be a problem in this context, requiring use of calcium supplements.

The few head-to-head studies suggest that anabolic agents have superior antifracture efficacy to bisphosphonates. Therefore, if available and affordable, a *PTH analog* or *romosozumab* could be first-line treatment options for a patient with a high fracture risk. Cost and the requirement for daily or monthly subcutaneous injections are the main downsides of this approach. Teriparatide has nil or negative effects on proximal femoral BMD in the first year of treatment, raising questions over its use as a first-line monotherapy in those at high risk of femoral neck or other cortical fractures.

Combination Therapy. Some of the largest increases in BMD have resulted from combination therapy with a PTH analog plus an antiresorptive. Whether the large BMD benefit translates into greater antifracture efficacy is unknown, but it is a strategy for consideration in the individual with markedly reduced BMD. Sequential therapy is a further way of deploying multiple agents to manage patients with severe osteoporosis. A variety of scenarios are possible. A common one is the patient who has further fractures while on treatment with an antiresorptive. Starting an anabolic agent in this situation is appealing, and bone density changes are more positive if the anabolic is added to the bisphosphonate rather than substituted for it. Switching from denosumab to teriparatide produces marked adverse effects on BMD, so is contraindicated.

A second scenario is that of a patient coming to the end of a course of an anabolic agent. Both PTH analogs and romosozumab show substantial offset of effects following discontinuation. Therefore, transition to another antiosteoporosis medication is appropriate, and this usually is an antiresorptive. Oral or intravenous bisphosphonates or denosumab have been shown to perform satisfactorily in this context. Raloxifene has been used following teriparatide and is superior to placebo in its BMD effects.

In summary, therapy usually starts with an oral or intravenous bisphosphonate, with denosumab being substituted if there are specific indications to do so. In severe disease, use of an anabolic as a first- or second-line therapy may be appropriate but will require transition to an antiresorptive at the end of the 1- or 2-year course.

How Long to Treat

Low BMD or high fracture risk are not self-limiting conditions, so lifelong management is likely to be needed. Management, however, may include periods off drug, made possible by the long duration of action of bisphosphonates, which continue to exert antiresorptive effects for months to years after their discontinuation.

Concern regarding atypical femoral fractures (and to a lesser extent ONJ), together with the long duration of effect of bisphosphonates, has led to the common practice of punctuating bisphosphonate treatment with *drug holidays*. The risk of atypical femoral fractures is 0.2 to 2 per 10,000 patient-years in the early years of bisphosphonate use but climbs steeply after 5 years of continuous treatment. Observational data suggest that risk is reduced by two-thirds in the months following bisphosphonate cessation and by almost 90% with a drug holiday of more than 15 months. Thus, it is common to withdraw alendronate for a period of 1 to 2 years after approximately 5 years of continuous therapy. Risedronate has a more rapid offset, and drug holidays of 6 to 12 months are recommended with that agent. Drug holidays are contraindicated with denosumab because of its rapid offset—denosumab requires transition to another antiresorptive drug, usually a bisphosphonate.

Practice with the long-term use of zoledronate varies. In the phase III clinical trial program, six annual infusions prevented more vertebral fractures than three annual infusions, the main benefit being in individuals whose femoral neck T-score was still less than –2.5 at the end of year 3. Extending annual infusions from 6 years to 9 years did not appear to confer benefit in terms of turnover markers, bone density, or fracture numbers, although the latter were small. Accordingly, many clinicians give three or six annual infusions of zoledronate, followed by a pause for several years. The present authors' practice is to initiate therapy at 18-month intervals for several years because this has been shown to produce comparable antifracture efficacy to annual dosing, and then to increase the interdose interval to 2 or 3 years subsequently if BMD response is satisfactory. In patients receiving this medication long-term, suppression of PINP (to 35–40 μg/L) and maintenance of BMD increases can be sustained over periods of more than a decade with injections every 3 to 5 years.[80]

Safety concerns (i.e., osteosarcoma) have limited the duration of use of PTH analogs to 18 to 24 months in most clinical trials. Transition to an antiresorptive agent at the end of this time is the conventional practice. The phase III trials of romosozumab only administered the drug for 12 months, and again transition to an antiresorptive is the recommended course.

Estrogen and SERMs have no specific time limits on their use, although the risk of breast cancer appears to increase linearly with duration of estrogen (but not SERM) exposure. These agents are not usually used as a primary therapy for osteoporosis.

Follow-Up

Practice varies with respect to the use of specific investigations during follow-up. In patients treated with oral bisphosphonates, it is wise to measure a bone turnover marker 3 to 6 months after initiation to ensure that the desired antiresorptive effect has been achieved. Serum PINP levels less than 35 to 40 μg/L are indicative of a satisfactory antiresorptive effect. Failure to do this could result in unsatisfactory dosing practices or low absorption of the drug not being detected until bone density is measured some years later. Many physicians remeasure BMD 3 to 5 years after treatment initiation. Measurement earlier than this is likely to be counterproductive in patients treated with antiresorptives because the expected changes are close to the precision limits of bone densitometers. Failure of BMD to increase during treatment raises the possibility of an underlying condition contributing to ongoing bone loss and suggests the need for appropriate investigations. In patients receiving oral agents, noncompliance and inadequate absorption of medication are the most common reasons for suboptimal BMD effects, so these problems should be detectable early in the course of treatment through measurement of a bone turnover marker.

KEY POINTS

- No single indication for treatment is universally accepted, although 3% 10-year hip fracture risk or 15%–20% major osteoporotic fracture risk are commonly used thresholds. With inexpensive generic bisphosphonates, treatment may be cost-effective at a 10-year hip fracture risk as low as 1%.

MANAGEMENT OF SUBTYPES OF OSTEOPOROSIS

Although the pathogenesis of *glucocorticoid-induced osteoporosis* is distinct from that of postmenopausal osteoporosis (see above), the principles of its management are similar. Fracture risk is evaluated based on demographic parameters, bone density, and current steroid dose. Further adjustment can be made for higher doses of steroids.[32] The range of medications is similar, as noted in Table 60.3. Studies in glucocorticoid osteoporosis have assessed BMD as the primary endpoint, and where fracture prevention has been observed, this is only for vertebral fracture.[81]

In premenopausal women and in men under 70 years with osteoporosis, it is important to make a thorough search for underlying causes of bone loss. As many as 50% of men will have some identifiable cause for their bone loss. Treatment efficacy data in men have the limitations noted above for glucocorticoid osteoporosis. There are very little trial data to address efficacy of treatments in premenopausal women, so management of these patients is not strictly evidence-based. However, the same sequence of treatment outlined for postmenopausal osteoporosis can be followed in these younger women, as long as underlying conditions have been sought and addressed, to the extent that this is possible.

Conclusion, 1047

In 2006, the disorders of mineral and bone metabolism in chronic kidney disease (CKD) were enshrined in a new syndrome called chronic kidney disease–mineral and bone disorder (CKD-MBD). The CKD-MBD name was coined by the Kidney Disease Improving Global Outcomes (KDIGO) foundation[1,2] for the syndrome associated with chronic kidney disease in which disorders of mineral metabolism and renal osteodystrophy (ROD) are key contributors to excess mortality.[3-6] The pandemic of CKD and end-stage kidney disease (ESKD) and the role of the CKD-MBD in the associated mortality make the syndrome a major health issue for Americans and all developed societies.[5,7-10] Recent advances define the CKD-MBD as a uniform complication of renal injury with wide variation in severity. The syndrome begins with renal injury early in CKD and contributes to the high mortality rates associated with CKD.[11] This chapter reviews recent pathophysiologic advances in the CKD-MBD and the classic pathophysiology of secondary hyperparathyroidism and ROD of CKD that have been incorporated into the syndrome. The result is the new understanding of a disordered systems biology involving the kidney, vasculature, heart, skeleton, and parathyroid glands in CKD, contributing mortality risk beyond that due to kidney disease itself (Fig. 61.1).[12]

KEY POINTS

- The chronic kidney disease–mineral and bone disorder is a syndrome incorporating the skeletal, vascular, and cardiac effects of chronic kidney disease as they are contributed by disorders in the metabolism of fibroblast growth factor 23, αKlotho, phosphate, calcium, vitamin D, parathyroid hormone, and activin receptor ligands.

PATHOBIOLOGY

Vascular

Vascular calcification (VC) is a strong risk factor for cardiovascular outcome in CKD.[13,14] The past few decades have seen extensive research into VC, revealing that the mechanism of VC is more than a consequence of a high-phosphorous milieu. In CKD, VC occurs via disordered biologic processes, including an imbalance between osteochondrogenic signaling and anticalcific events. In addition to traditionally established osteogenic signaling, dysfunctional calcium homeostasis is a prerequisite in the development of VC. Moreover,

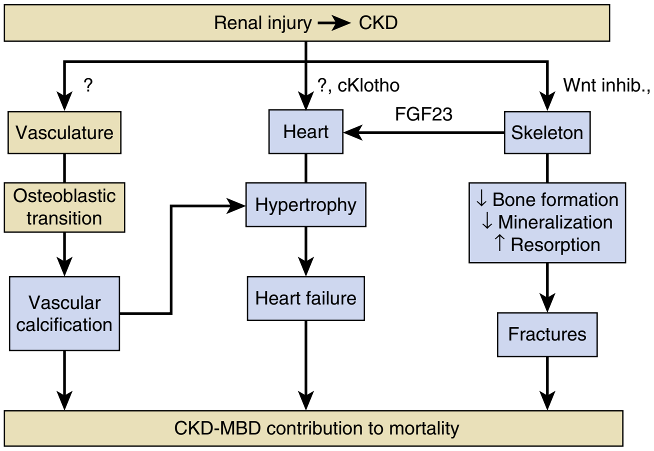

Figure 61.1 The disordered systems biology of the chronic kidney disease–mineral and bone disorder (CKD-MBD). A multiorgan systems biology "wired" together in part by circulating communications is disordered in chronic kidney disease (CKD). Renal injury increases circulating levels of factors affecting multiple organs peripheral to the kidneys. Key among these are the vasculature affecting very early in kidney disease by osteoblastic transition of cells in vessel walls; the heart's cardiomyocytes, which undergo hypertrophy due to a multitude of factors, including: 1) unknown in nature, 2) due to vascular stiffness produced in part by vascular calcification, and 3) by high levels of fibroblast growth factor 23 acting through fibroblast growth factor receptor 4.[87] The skeleton is immediately impacted during attempted renal repair by inhibitors of bone formation such as Dickkopf-1 and other Wnt inhibitors. The effects of peripheral organ damage lead to secondary pathologies of vascular calcification, cardiac hypertrophy, and renal osteodystrophy, culminating in the contributions of the CKD-MBD to the exaggerated mortality of CKD.

loss of defense mechanisms, by microorganelle dysfunction, including hyperfragmented mitochondria, mitochondrial oxidative stress, defective autophagy or mitophagy, and endoplasmic reticulum stress, may all contribute to VC.

Abnormalities of the vasculature found in early CKD produce vascular stiffness and contribute to left ventricular hypertrophy.[15,16] In addition, osteoblastic transition in arterial walls during early CKD progresses to VC.[17,18] VC further intensifies stiffness and development of left ventricular hypertrophy, all processes that contribute to cardiovascular risk and excess cardiac mortality. However, CKD directly stimulates cardiac hypertrophy independent of arterial stiffness, further contributing to mortality.[19]

The pathogenesis of VC in CKD is complex,[20] and pathologically is of two types: neointimal and arterial medial. The pathogenesis of atherosclerotic neointimal calcification is multifactorial, but it involves activation of an osteoblastic differentiation program in cells of the neointima of atherosclerotic plaques[2122] and in cells of arterial media. Diffuse calcification of the arterial tunica media is referred to as Mönckeberg sclerosis.[23] CKD is the most common cause of Mönckeberg sclerosis, especially when it complicates diabetes mellitus. In translational models of atherosclerosis and diabetes (low-density lipoprotein receptor deficiency [*ldlr-/-*] with high-fat feeding), mild renal insufficiency (equivalent to human stage 2 CKD) reduces the levels of aortic proteins involved in the contractile apparatus of smooth muscle.[17] This, coupled with evidence that vascular smooth muscle cells move into a dedifferentiated synthetic state from their normal contractile differentiated state,[24] represents significant evidence of large artery smooth muscle dedifferentiation in very early diabetic CKD.[25] Within the developmental program of mesenchymal stem cells and early progenitor cells, dedifferentiated vascular smooth muscle cells are susceptible to transition to the differentiation program of osteoblasts, which causes VC in CKD.[23] Osteoblastic transition of cells in the arterial walls produces CKD stimulated calcification of atherosclerotic plaques and the vascular media.[18,21,23,26-28] The source of these cells may be mesenchymal progenitors from the adventia moving into the media and expressing both smooth muscle and osteoblastic transcriptional programs,[29] although other lineage tracing studies support vascular smooth muscle cells.[30,31]

KEY POINTS

- Vascular calcification (VC) is highly prevalent in chronic kidney disease. The calcifications are in the media of large and medium arteries and in the neointima of atherosclerotic plaques. In the heart, coronary arteries and valves, especially aortic, are affected. VC is a major cause of arterial stiffness contributing to cardiac hypertrophy. VC is produced by osteoblastic differentiation of cells in the vascular wall and by disordered mineral metabolism producing the skeletal paradox of decreased orthotopic mineralization (deposition of hydroxylapatite in bone) and increased heterotopic mineralization (VC).

Cardiac

Cardiac hypertrophy is highly prevalent in CKD. We found in a cohort of patients with CKD stage 3 from a single-center clinic and a mean estimated glomerular filtration rate (eGFR) of 50 ml/min/mm^2, an 80% incidence of left ventricular hypertrophy by computed tomography scanning.[32] This is in concert with larger population studies.[7,19] Cardiac hypertrophy is an early stage of cardiovascular disease leading to high rates of heart failure, sudden death, and even ischemic myocardial infarction.[7] The causes of cardiac hypertrophy in CKD are multifactorial including hypertension, anemia, vascular stiffness, fibroblast growth factor 23 (FGF23),[33] and decreased αKlotho—the latter three are components of the CKD-MBD (Fig. 61.2). Vascular stiffness is a result of VC, vascular remodeling, and vascular smooth muscle dedifferentiation. The high levels of FGF23 causing cardiomyocyte hypertrophy are also late in CKD compared with the early elevations in FGF23 referred to above and elsewhere in this chapter.[34] We have found a new and novel cause of cardiac hypertrophy in our studies of activin receptor stimulation in CKD.[18,35] In three mouse models of CKD, cardiac hypertrophy develops during CKD with reductions in eGFR equivalent to human CKD stage 3. Inhibition of activin receptor type 2A prevents cardiac hypertrophy, despite not affecting FGF23 levels or fully restoring circulating Klotho.[18,35] The mechanism of this effect will introduce a new therapeutic target for cardiovascular disease in CKD and the CKD-MBD.

KEY POINTS

- The chronic kidney disease–mineral and bone disorder (CKD-MBD) contributes nontraditional risk factors to the elevated cardiovascular morbidity/mortality associated with chronic kidney disease (CKD). Cardiac hypertrophy is highly prevalent in CKD, and it leads to heart failure with both preserved and decreased ejection fraction. It contributes to arrhythmias and sudden death. Several components of the CKD-MBD (FGF23, circulating Klotho, vascular stiffness, and activin receptor activation) contribute to cardiac hypertrophy and cardiovascular risk. These direct cardiac effects of the CKD-MBD brings cardiovascular disease into the CKD-MBD syndrome.

Skeletal

Abnormalities of bone in the CKD-MBD begin with the renal response to injury due to activation of Wnt pathways in the kidney.[36,37]

Figure 61.2 The disordered systems biology of the chronic kidney disease–mineral and bone disorder (CKD-MBD) (part 2). A multiorgan systems biology "wired" together in part by circulating communications is disordered in chronic kidney disease (CKD). Kidney injury leading to CKD increases levels of some factors reaching the circulation such as the Wnt inhibitor family, and decreases others such a αKlotho. Renal αKlotho is a transmembrane protein whose extracellular domain is cleaved by ADAMS 10 and 17,[80] producing circulating Klotho, whose hormonal functions include regulation of fibroblast growth factor 23 (FGF23) secretion by skeletal osteocytes.[79,80] The decrease in αKlotho produced by renal injury immediately disorders regulation of FGF23 secretion. The increases in FGF23 affect proximal tubular phosphate excretion and calcitriol production through activation of fibroblast growth factor receptor 1C through the coreceptor function of αKlotho.[202,203] The loss of Klotho disorders phosphate excretion,[100,103] leading to hyperphosphatemia, calcitriol deficiency, hypocalcemia, and hypeparathyroidism as kidney disease progresses. Hyperphosphatemia stimulates vascular calcification already in progress from osteoblastic transition.[122,204] CKD activation of activin receptor signaling systemically has been shown to contribute to vascular calcification, decreased bone formation, increased bone resorption, and cardiac hypertrophy without affecting FGF23 but increasing αKlotho.[18,35,47]

Canonical Wnt signaling transcriptionally stimulates production of multiple Wnt inhibitors, which are secreted systemic factors.[38,39] As a result, kidney injury directly inhibits bone remodeling, which is homeostatically Wnt-dependent (see Fig. 61.2).[40-42] Skeletal inhibition of β-catenin signaling and increased expression of osteocytic FGF23 are seen after a relatively mild reduction in the eGFR, stage 2 CKD.[43-45] These abnormalities affect cortical bone predominately in early CKD and progress to decreased cortical bone volume and porosity.[17] Abnormalities of remodeling, mineralization, and the material properties of bone develop in CKD, leading to major decreases in structural strength, fractures, and deformity associated with long-term disease (see Fig. 61.1).[46] Recent studies demonstrate the progressive development of a remodeling imbalance during CKD due to stimulation of osteoclast number and function, but a relative decrease in osteoblast function in view of increased osteoblast number that fails to increase bone formation as expected.[18,47] This is fueled by hyperparathyroidism in collaboration with activin/activin receptor type II signaling (see Fig. 61.2).[18] The progression of the skeletal remodeling disorder in CKD to the familiar high-turnover state related to hyperparathyroidism begins from a low-turnover state produced by CKD induced Wnt inhibition in early CKD.[39,44,45]

KEY POINTS

- The skeleton was the first organ shown to be affected by release of renal repair or injury factors from the kidney—the Wnt inhibitors. This established the paradigm that renal injury/repair produces systemic disease through release of factors to the circulation and loss of other factors. How early chronic kidney disease causes increased secretion of FGF23 and sclerostin from skeletal osteocytes remains unclear. Loss of hormonal circulating Klotho contributes to protean homeostatic disturbances.

Plasma

In addition, elevated FGF23 and sclerostin levels largely from osteocytes (although the diseased kidney produces sclerostin[48]) and elevated parathyroid hormone (PTH) levels are observed in early CKD before detectable changes in the serum inorganic phosphate (Pi), calcium, or calcitriol levels.[49-51] The early increase in FGF23 in CKD[43,49] makes it a powerful biomarker, indicating that renal injury has affected osteocyte function and secretion.[43] If the hyperparathyroidism of early CKD is prevented, the prevalence of a low turnover osteodystrophy (the adynamic bone disorder) increases, further demonstrating the effects of kidney injury on the skeleton.[52] By the time ESKD develops, skeletal pathology is nearly universally present.[53]

PATHOGENESIS

The response to renal injury early in CKD causes the CKD-MBD. Three effects of early CKD stand out from studies over the past two decades. First, renal injuries produce circulating signals that affect the vasculature, the skeleton, and the myocardium. Second, skeletal osteocytes increase FGF23 secretion. Third, reductions in renal αKlotho affect the hormonal soluble Klotho in the circulation (cKlotho) (see Fig. 61.1). Renal injury and disease produce reactivation of developmental programs of nephrogenesis in an attempt at kidney repair. These programs are generally silent in the normal adult human kidney. The best-studied example is the reactivation of the Wingless/Integration 1 (Wnt, a portmanteau of Wg and int) pathway[54,55] that controls tubular epithelial differentiation, proliferation, and polarity during nephrogenesis.[56-60] Wnt reactivation is a driving force in renal fibrosis in disease.[61-63] In the canonical Wnt signaling pathway, the transcriptional targets include a complex family of inhibitory proteins,[64] the Wnt inhibitors, including Dickkopf-1 (Dkk1),[65] soluble frizzled-related proteins, and sclerostin.[48] While Wnts are strictly autocrine/paracrine factors,[66] the Wnt inhibitors are secreted/circulating proteins.[67] The role of Wnt in renal development largely precedes the invasion of the microcirculation forming the glomerulus and the peritubular capillaries. Thus, the Wnt inhibitors are not circulating humoral substances produced by the normal kidney. Their release into the circulation during kidney injury/repair represents a systemic pathologic insult inhibiting the physiologic roles of Wnt in the rest of the body. This has been shown to have major consequences in the vasculature and the skeleton.[39,45,68]

The role of the Wnt inhibitor families in vascular function during early kidney disease was recently demonstrated by finding significantly increased renal expression of Wnt inhibitors in the injured kidney,[39,54] their increased presence in the circulation,[39] and the inhibition of one, Dkk1 by a monoclonal antibody.[39] Dkk1 neutralization was sufficient to decrease the CKD-stimulated dedifferentiation of the vasculature. Dedifferentiation was shown by decreased expression levels of proteins involved in smooth muscle contraction. Dkk1 neutralization increased smooth muscle contractile protein levels and inhibited osteoblastic transition. The levels of Runx2, the critical osteoblast transcription factor, and its transcriptional targets were decreased by Dkk1 neutralization, and the expression of Klotho was increased. The result was that Dkk1 neutralization inhibited stimulation of vascular calcium levels in an atherosclerotic calcification model stimulated by early CKD.[17,39]

The skeleton is especially sensitive to circulating Wnt inhibition, because Wnts have been shown to be a major stimuli of normal skeletal remodeling.[69] Genetic diseases produced by activating mutations in the Wnt coreceptor proteins low-density lipoprotein receptor–related proteins 5 and 6 (LRP5/6)[42,70] and by inactivating mutations in Wnt inhibitor proteins, such as sclerostin, involved in the pathogenesis of sclerosteosis[71,72] and van Buchem disease demonstrate the critical role of Wnt in skeletal remodeling and bone formation.[73] Wnts are also critical factors of the hematopoietic stem cell niche,[66,74,75] and their inhibition through circulating Wnt inhibitors is not tolerable, leading to adaptive production of another niche factor, PTH.[76,77] The adaptive increase in PTH prevents the expected inhibition of skeletal remodeling produced by circulating Wnt inhibitors.[45] Therefore, low-turnover osteodystrophy is not a generalized observation in early CKD, but it is observed when the increase in PTH is prevented.[52] In a preclinical model of atherosclerosis and type 2 diabetes, early CKD additively suppresses bone formation rates, especially in cortical bone, that is reversed by Dkk1 neutralization.[39]

Early CKD stimulates osteocyte production of FGF23 and sclerostin.[43,49] Recent studies show that the combination of dietary phosphate restriction and phosphate binders decreased FGF23 levels in early CKD with normophosphatemia.[78] The concept that changes in urinary (tubular fluid) phosphate regulates osteocytic FGF23 secretion is in agreement with the demonstrated hormonal function of cKlotho.[79] The physiologic paradigm is that regulation of disintergin metalloproteases ADAMS 10 and 17 by tubular fluid phosphate affects cleavage of membrane Klotho, producing the hormone cKlotho. In turn, cKlotho regulates osteocyte secretion of FGF23.[80] The problem with the physiologic system is that CKD decreases tubular epithelial membrane Klotho levels,[81] eliminating the adaptive potential of increasing cKlotho levels in CKD and relegating regulation of FGF23 secretion to increases in S[P] and other mechanisms. The stimulation of FGF23 and sclerostin in early CKD produce an inhibition to skeletal remodeling that becomes a background as adaptive hyperparathyroidism maintains and even increases bone remodeling rates.[45,82] In addition to FGF23, the increase in sclerostin in early CKD represents biomarker evidence of skeletal inhibition produced by renal injury. The loss of skeletal anabolism in CKD occurs in the presence of normal PTH, vitamin D, S[Ca], and S[P] levels, but it is not usually observed as the adynamic bone disorder, because disturbed homeostasis in these factors stimulates PTH secretion. The sustained increase in PTH levels produced through adaptation to CKD increases remodeling rates and eventually produces an unwanted high-turnover disorder of skeletal remodeling, osteitis firbosa.

PATHOGENIC FACTORS IN THE CHRONIC KIDNEY DISEASE–MINERAL AND BONE DISORDER

FGF23

FGF23 is the original phosphatonin (phosphate excretion–regulating hormone) discovered in studies of autosomal dominant hypophosphatemic rickets and oncogenic osteomalacia.[83,84] FGF23 is a bone-derived (osteocyte) hormone that regulates phosphorus balance by enhancing urinary phosphorus excretion and inhibiting the synthesis of 1’,25-dihydroxyvitamin D (1’,25(OH)2D). FGF23 plays an important role in maintaining phosphorus balance in states of phosphorus excess such as CKD.[85] FGF23 concentrations increase early in kidney failure and steadily rise with kidney function decline. Although this represents an appropriate physiologic response to maintain normal phosphorus balance, an important consequence is progressive 1,25(OH)$_2$D decline. Thus, while increased FGF23 secretion may be critical for avoiding phosphorus overload in early CKD, the tradeoff of lower 1,25(OH)$_2$D supports the notion that increased FGF23 may be the key factor underlying the genesis of secondary hyperparathyroidism in CKD.

Epidemiologic data have established that higher FGF23 concentrations are independently associated with higher risk of cardiovascular disease events and death in individuals across the spectrum of kidney function.[86] High FGF23 concentrations are strongly associated with higher left ventricular mass, independent of blood pressure and kidney function.[87] In addition, FGF23 induces hypertrophy of cardiomyocytes *in vitro* and *in vivo*,[87] both through fibroblast growth factor receptor (FGFR)–mediated stimulation of hypertrophy[87] and through disturbances in calcium handling in cardiac cells.[88] The prohypertrophic effects of FGF23 on cardiomyocytes are mediated by binding of FGF23 to FGFR4, even in the absence of Klotho, which activates phospholipase Cγ/calcineurin/NF of activated T-cell signaling.[89] The adverse effects of elevated FGF23 on cardiac hypertrophy in animals with experimentally induced CKD were partially reversible through targeted blockade of FGF23 binding to FGFR4 without precipitating hyperphosphatemia.[88] More recent data show that FGF23 can adversely affect cardiovascular health by stimulating sodium retention, upregulating the renin-angiotensin-aldosterone system, and enhancing the arrhythmogenic potential of heart cells via disruption of calcium trafficking.[88] These data provide clinical and mechanistic evidence for a direct link between higher FGF23 and cardiovascular disease. However, they are not without controversy,[90] and randomized trials that target pathways shown to be involved in the pathophysiology of FGF23-induced cardiovascular disease are necessary.[91]

KEY POINTS

- Fibroblast growth factor 23 (FGF23) is a relatively new hormone that was discovered in 2000. It is a major regulator of renal phosphate excretion, establishing the paradigm that signals emanating from the skeletal reservoir regulate phosphate excretion. FGF23 is dysregulated early in renal injury—both acute kidney injury and chronic kidney disease (CKD). Its elevations are a strong biomarker of cardiovascular outcome including mortality. FGF23 signals through fibroblast growth factor receptor (FGFR) requiring a coreceptor αKlotho, except for FGFR4, especially in the heart. Cardiac FGF23 effects include cardiac hypertrophy in CKD.

Klotho

αKlotho (Klotho hereafter) is highly expressed in the kidney as a transmembrane protein. In membrane-bound form, Klotho serves as a requisite coreceptor for FGF23 in conjunction with FGFRs.[92] Secondly, Klotho is a single–transmembrane pass protein with a large extracellular domain that possesses homology with glycosidases and functions as a glucuronidase and a sialidase.[93,94] FGF23 signaling through FGFRs requires the coreceptor function of Klotho. High Klotho expression has very limited tissue distribution, defining the tissue targets of FGF23 as a hormone.[95,96] These targets are the proximal and distal renal tubules, the parathyroid glands, and the brain.[95,97] Cleavage of the extracellular domain of Klotho[80] and its shedding into the urine and blood suggested hormonal function of the protein.[98,99] This was defined by its function in FGF23 secretion by osteocytes.[79] Soluble cKlotho acts as an endocrine or paracrine factor affecting multiple organs, such as the kidney, bone, brain, heart, lungs, and endothelium.[100-102]

Due to the major decrease in Klotho expression produced by renal injury,[103,104] the role of cKlotho in osteocyte regulation is limited.[102] This leaves hyperphosphatemia as the main regulator of FGF23 secretion in CKD. Furthermore, the loss of Klotho expression in CKD limits FGF23-stimulated signal transduction through FGFR/Klotho complexes. One result is the loss of negative feedback to FGF23 secretion and the continual production of FGF23 and secretion by the osteocyte. In late CKD, the very high levels of FGF23 permit anomalous FGFR activation independent of Klotho. This results in FGF23-stimulated pathologic stimuli such as cardiac myocyte hypertrophy (see Fig. 61.2).[87]

FGF23 suppresses PTH secretion and *PTH* gene expression through FGFR/Klotho signaling,[97] and PTH affects FGF23 secretion. This physiologic system of osteocyte-parathyroid and parathyroid-osteocyte regulation does not operate appropriately in CKD,[105] and the kidney-osteocyte, osteocyte-kidney signaling for phosphate homeostasis is not adaptive in CKD.

Experimental data establish a clear relationship between Klotho and the cardiovascular system. *Klotho*-null mice develop CKD-like cardiovascular phenotypes, such as VC, cardiac hypertrophy, and fibrosis. However, Klotho mRNA is not detected in the myocardium, aside from the sinoatrial node. Thus, loss of Klotho in the myocardium may not directly contribute to cardiac hypertrophy. Leifheit-Nestler et al.[106] revealed the presence of Klotho protein in cardiac muscle, which suggests that the heart can take up soluble Klotho from the circulation. A series of studies found that soluble Klotho inhibits the prohypertrophic signaling pathway and exerts unique biologic functions that are independent of FGF23.[107] For example, soluble Klotho directly binds to the type II transforming growth factor (TGF)-β receptor,[108] blocking TGF-β1 signaling. TGF-β1 is highly involved in cardiac hypertrophy.

Intriguingly, cKlotho suppresses cardiac hypertrophy that is induced by Ang-II, TGF-β, or isoprenaline.[109] Thus, cKlotho demonstrates a broad spectrum of antihypertrophic effects. Soluble Klotho inhibits the production of reactive oxygen species (ROS), and cKlotho deficiency may lead to an increase in ROS in myocardial tissue and induce cardiac hypertrophy.[110] In addition, several signaling pathways that may be involved in CKD-induced cardiac injury, including the PI3K, Wnt, and NF-κB pathways, can be regulated by cKlotho. Recently, a specific receptor for soluble Klotho, monosialoganglioside, was identified; cKlotho binds to it and inhibits raft-dependent PI3K signaling.[111] These studies show that soluble Klotho can inhibit the translocation of transient receptor potential cation channel, subfamily C, member 6 (TRPC6), an ion channel that is involved in the formation of cardiac hypertrophy.

KEY POINTS

- αKlotho is factor with widespread homeostatic functions. Most circulating Klotho (cKlotho) comes from the kidney, where the extracellular domain of renal tubular membrane Klotho is cleaved, producing the hormonal cKlotho. Membrane Klotho is the coreceptor with the fibroblast growth factor receptors for fibroblast growth factor 23 (FGF23). cKlotho regulates FGF23 secretion. cKlotho is a key cardiac homeostatic factor, and its loss in chronic kidney disease contributes to cardiac hypertrophy, vascular calcification, and osteoporosis.

Sclerostin

Sclerostin is a 22-kDa glycoprotein encoded by the *SOST* gene. Except in CKD, sclerostin is almost exclusively synthesized by osteocytes that are not present near the bone surface, but lie in the mineralized cortical and cancellous bone. Sclerostin can exert its inhibitory effects on bone formation not only by inhibiting the proliferation, differentiation, and function of osteoblast cells, but also by facilitating their apoptosis. Wnt/β-catenin signalling pathway participates in the pathogenesis of atherosclerosis and VC. Serum sclerostin levels in CKD patients are remarkably higher than those in the normal population, with their values increasing across the CKD stages. However, studies on the association of serum sclerostin with VC and mortality in renal disease patients have yielded conflicting results. Some investigations showed a positive correlation, whereas others suggested no or even negative correlation. VC occurs frequently in CKD patients, and its incidence increases across the CKD stages. Notably, VC is associated with cardiovascular events and poor prognosis in CKD. It is well-recognized that VC occurs in the early years of kidney disease, even prior to the occurrence of disordered phosphate homeostasis. VC is recognized as a pathological process of osteogenesis initiated by inflammatory factors in vessels. The upregulation of sclerostin in calcified tissues led to the hypothesis that sclerostin may be related to the pathogenic mechanism of VC in renal disease patients, leading to a large number of studies examining the association between sclerostin and VC in CKD patients. However, these studies reported inconsistent results, with some studies showing a positive association between sclerostin and VC in CKD patients, whereas others showing a negative association or no association at all.

As described above, Wnt signaling activity is a major player in physiological and adaptive bone metabolism. Wnt signaling is regulated by soluble inhibitors, with sclerostin being the most widely studied. Sclerostin's main origin is the osteocyte, and its major function is blockade of osteoblast differentiation and function. Therefore, sclerostin is a potent inhibitor of bone formation and mineralization. Consequently, blocking sclerostin via human monoclonal antibodies represents a new therapy for the treatment of postmenopausal osteoporosis,[112,113] and will be used in the treatment of ROD. In preclinical studies, sclerostin antibodies were effective in enhancing bone mass and ameliorating mechanical properties only if hyperparathyroidism was treated sufficiently by high calcium intake.[114] Only in the low-PTH group did sclerostin antibody treatment reveal remarkable changes in ROD, as evidenced by an increased cortical thickness and bone volume, as well as an increase in bone quality/strength (as measured by ultimate load and energy to failure).[114] However, sclerostin's physiology and the effects of sclerostin monoclonal antibody treatment are not limited to the skeleton. Specifically, the potential roles of sclerostin in CKD and associated pathologies of the CKD-MBD, including accelerated cardiovascular calcification, warrant specific attention. In the CKD-MBD, sclerostin antibodies may interfere at different levels and influence the multiform interplay of hyperparathyroidism, ROD, and VC, but the clinical sequelae remain obscure.[115] Research targets have been identified that need to be addressed before a valid risk/benefit ratio for sclerostin antibodies can be established in the clinical setting of CKD.

Hyperphosphatemia

As renal injury decreases nephron number, phosphate excretion is maintained by reductions in the fraction of filtered phosphate reabsorbed by the remaining nephrons under the influence of FGF23 and PTH.[116] The effects of FGF23 stimulated by cKlotho before changes in S[P] are limited by the loss of proximal tubular Klotho.[103] The combination of FGF23's and PTH's effects to decrease proximal tubular phosphate reabsorption are sufficient to maintain phosphate homeostasis through stage 3 to stage 4 CKD when hyperphosphatemia ensues.[105] This is at the cost of higher PTH and FGF23 levels. In stage 4 and stage 5 CKD, when renal injury is severe enough that the eGFR reaches levels of less than 30% of normal, hyperphosphatemia develops due to decreased renal [P] excretion despite high PTH and FGF23 levels.[105,117]

Studies demonstrate that failure of calcium and phosphorus deposition into the skeleton or excess resorption of the skeleton also contribute to abnormal S[P] and S[Ca] levels in CKD and end-stage renal disease (ESRD).[118-120] The skeleton contributes to the pathogenesis of VC through contributing to hyperphosphatemia.[16,118] Signals deriving from the skeleton are direct causes of vascular mineralization. The best-documented signal deriving from the skeleton is hyperphosphatemia.[121,122] Hyperphosphatemia stimulates osteoblastic transition in the vasculature[122,123] and directly contributes to mineralization through the calcium-phosphorus product (see Fig. 61.2).[121] Phosphorus is a signaling mechanism working through the Pit 1 and 2 sodium phosphate cotransport proteins as receptors for stimulation of MAP kinase signal transduction and stimulation of heterotopic mineralization of the vasculature in CKD.[121,124]

Hyperphosphatemia also decreases S[Ca] through physicochemical complexation and suppresses 1α-hydroxylase activity, which results in further lowering of circulating calcitriol levels (see Fig. 61.2). Moreover, a direct stimulatory effect of phosphorus on parathyroid gland cells, independent of S[Ca] and calcitriol levels, produces increased secretion and nodular hyperplasia of parathyroid gland cells (see Fig. 61.2).[125,126] A direct stimulatory effect of Pi, perhaps in the exchangeable Pi pool, regulates osteocyte FGF23 secretion.

Treatment of hyperphosphatemia employs a series of chemical salts that bind Pi with varying affinity and capacity. The clinical outcomes of this approach have been disappointing, and the reductions of serum Pi are usually approximately 1 mg/dL. In CKD predialysis, phosphate binders have been especially disappointing. The results of the IMPROVE-CKD trial are likely to lead to reduction in their use prior to dialysis.[127]

KEY POINTS

- Hyperphosphatemia develops in stage 4 chronic kidney disease (CKD) due to loss of fibroblast growth factor 23 and parathyroid hormone (PTH) effectiveness. Recent studies prove that stimulation of phosphate excretion in late CKD could control serum phosphate normal.[205] Hyperphosphatemia signals through the Pit class of phosphate transporters to stimulate vascular osteoblastic cells to mineralize the extracellular matrix (vascular calcification). Hyperphosphatemia also stimulates PTH secretion.

Calcitriol Deficiency

The physiologic actions of FGF23 from the osteocyte include inhibition of proximal tubular CYP27B1, 25-OH vitamin D 1α hydroxylase, and stimulation of CYP24A1, vitamin D 24-hydroxylase, decreasing calcitriol production and producing vitamin D deficiency in early CKD (see Fig. 61.2). As CKD advances, the functioning nephron mass is decreased, and this, combined with an increased phosphate load in the remaining nephrons and increased FGF23 levels, results in calcitriol deficiency.[128] Calcitriol deficiency in turn decreases intestinal calcium absorption, leads to the development of hypocalcemia, and produces increased *PTH* gene transcription. Calcitriol deficiency in cases of advanced CKD diminishes tissue levels of vitamin D receptors (VDR), in particular, the VDR of parathyroid gland cells.[129] Because the chief cell VDR suppresses the expression of prepro-PTH mRNA, lower circulating calcitriol levels, together with a low number of VDRs, in patients with ESRD result in stimulation of both synthesis and secretion of PTH[130] and resistance to the effects of calcitriol. The hypocalcemia in stage 5 CKD resulting from these pathophysiologic processes unchecked by medical intervention is severe and resistant to therapy with calcium and calcitriol supplementation, due to VDR deficiency.

KEY POINTS

- Due to the actions of fibroblast growth factor 23 to inhibit the 1α hydroxylase and stimulate the 24-hydroxylase, vitamin D and calcitriol are prevalent in chronic kidney disease. This stimulates parathyroid hormone secretion and eventually leads to hypocalcemia.

Hypocalcemia

As CKD progresses, hypocalcemia develops due to decreased intestinal calcium absorption. Low blood levels of ionized calcium stimulate, while high S[Ca] suppresses, PTH secretion. The action of calcium on parathyroid gland chief cells is mediated through a calcium sensor (calcium-sensing receptor [CASR]), a G protein–coupled plasma membrane receptor expressed in chief cells and kidney tubular epithelia and widely throughout the body at lower levels.[131,132] The short-term stimulation of PTH secretion induced by low S[Ca] is due to exocytosis of PTH packaged in granules, and longer-term stimulation results from an increase in the number of cells that secrete PTH. More prolonged hypocalcemia induces changes in intracellular PTH degradation and mobilization of a secondary storage pool. Within days or weeks of the onset of hypocalcemia, prepro-PTH mRNA expression is stimulated. This effect is exerted through a negative calcium response element located in the upstream flanking region of the gene encoding PTH. Expression of the calcium receptor has been shown to be suppressed by calcitriol deficiency and stimulated by calcitriol administration, suggesting an additional regulatory mechanism of the active vitamin D metabolite on PTH production. The decreased number of CASRs with low circulating calcitriol may, at least in part, explain the relative insensitivity of parathyroid gland cells to calcium in patients undergoing dialysis.

Hyperparathyroidism

All of the mechanisms discussed above result in increased production of PTH and nodular hyperplasia of the parathyroid glands in CKD. The size of the parathyroid glands progressively increases during CKD and in dialyzed patients, paralleling serum PTH levels. This increase in gland size is mainly due to diffuse cellular hyperplasia. Monoclonal chief cell growth also develops, resulting in the formation of nodules. Nodular hyperplastic glands have fewer VDRs and CASRs compared with diffusely hyperplastic glands, promoting parathyroid gland resistance to calcitriol and calcium. Sustained elevation in PTH levels, while adaptive to maintain osteoblast surfaces, produces an abnormal phenotype of osteoblast function and osteocyte stimulation, with relatively less type 1 collagen and more RANKL production than anabolic osteoblasts. A key component of the RANKL stimulation is osteocytic in origin. This leads to a high-turnover osteodystrophy, PTH receptor desensitization, and excess bone resorption.

Hypogonadism

Patients with ESRD have various states of gonadal dysfunction.[133-135] Estrogen and testosterone deficiency significantly contribute to the pathogenesis of ROD.[136,137].

Other Factors

Inflammatory mediators, acidosis[138,139], aluminum, leptin and retained catabolites are all potentially critical factors in the CKD-MBD that have not been well studied, or recently have become less important clinically. Some patients with CKD are treated with glucocorticoids, which affect bone metabolism. Patients maintained on chronic dialysis have retention of β2- microglobulin. Additionally, alterations in growth factors and other hormones involved in the regulation of bone remodeling may be disordered in CKD and ESRD, thus affecting bone remodeling and contributing to the development of ROD.

PATHOLOGY OF RENAL OSTEODYSTROPHY

With the advent of the CKD-MBD syndrome, the term ROD is restricted to the skeletal pathology of CKD and the modeling/remodeling disorders it causes. ROD is not a uniform disease. Depending on the relative contribution of the different pathogenic factors discussed above and their treatment, various pathologic patterns of bone remodeling are expressed in CKD and ESRD patients.[140]

Predominant Hyperparathyroid Bone Disease, High-Turnover Renal Osteodystrophy, Osteitis Fibrosa

Sustained excess PTH action results in increased bone turnover.[140-144] Osteoclasts, osteoblasts, and osteocytes are found in abundance. Disturbed osteoblastic activity results in a disorderly production of collagen, which results in formation of woven bone.[145] Accumulation of fibroblastic osteoprogenitors not in the osteoblastic differentiation program results in collagen deposition and in the development of fibrosis in the peritrabecular and marrow space.[27,140,146] The nonmineralized component of bone, osteoid, is increased, and the normal three-dimensional architecture of osteoid is frequently lost.[147] Osteoid seams no longer exhibit their usual birefringence under polarized light. Instead, a disorderly arrangement of woven osteoid and woven bone with a typical crisscross pattern under polarized light is seen. The mineral apposition rate and number of actively mineralizing sites are increased, as documented under fluorescent light after the administration of time-spaced fluorescent (tetracycline) markers.[148]

Low-Turnover Bone Disease, Adynamic Bone Disorder

Low-turnover uremic osteodystrophy is the other end of the spectrum of ROD.[149] The histologic hallmark of these disorders is a profound decrease in bone turnover, due to a low number of active remodeling sites and suppression of bone formation and resorption.[150,151] Bone resorption is not as decreased as formation. The result is a low-turnover osteopenic condition. The majority of trabecular bone is covered by lining cells, with few osteoclasts and osteoblasts. Bone structure is predominantly lamellar. The extent of mineralizing surfaces is markedly reduced. Usually only a few thin, single tetracycline labels are observed. Two subgroups can be identified in this type of ROD, depending on the cause of events leading to a decline in osteoblast activity: first, the adynamic bone disorder, and second, low-turnover osteomalacia from aluminum intoxication, bisphosphonate administration, or other factors.[152-154]

We postulated that the adynamic bone disorder was caused by loss of skeletal anabolic activity,[140] which has subsequently been shown to be true. First, we demonstrated that, following renal injury, if S[C], S[P], PTH, and calcitriol were maintained at normal levels, the adynamic bone disorder resulted,[52] and that it was corrected by a skeletal anabolic factor made in the normal kidney. Subsequently, we demonstrated that renal diseases increase inhibitors of Wnt in the systemic circulation,[39] and Sabbagh et al. showed that skeletal Wnt activity was suppressed in early CKD.[45] More recently, we showed that neutralization of a key Wnt inhibitor, Dkk1, was sufficient to correct the low-turnover osteodystrophy seen in a model of type 2 diabetes and early CKD.[39] In this model with further aging, resistance to PTH action is overcome by very high PTH levels, and the osteodystrophy begins to convert to higher turnover rates. Thus, the complex pathophysiology of ROD has been further clarified.

Low-turnover osteomalacia is characterized by an accumulation of unmineralized matrix in which a diminution in mineralization precedes or is more pronounced than the inhibition of collagen deposition.[155-158] Unmineralized bone represents a sizable fraction of trabecular bone volume. The increased lamellar osteoid volume is due to the presence of wide osteoid seams that cover a large portion of the trabecular surface. The occasional presence of woven bone buried within the trabeculae indicates past high bone turnover. When osteoclasts are present, they are usually seen within trabecular bone or at the small fraction of trabecular surface left without osteoid coating.

Mixed Uremic Osteodystrophy, High-Turnover Renal Osteodystrophy Plus a Mineralization Defect

Mixed uremic osteodystrophy is caused primarily by hyperparathyroidism and defective mineralization with or without increased bone formation.[148,151,155] These features may coexist in varying degrees in different patients. Increased numbers of heterogeneous remodeling sites can be seen. The number of osteoclasts is usually increased. Because active foci with numerous cells, woven osteoid seams, and peritrabecular fibrosis coexist next to lamellar sites with more reduced activity, greater production of lamellar or woven osteoid causes an accumulation of osteoid with normal or increased thickness of osteoid seams. While active mineralizing surfaces increase in woven bone with a higher mineralization rate and diffuse labeling, mineralization surfaces may be reduced in lamellar bone with a decreased mineral apposition rate.

ASSOCIATED FEATURES

Osteoporosis and Osteosclerosis

With progressive loss of renal function, cancellous bone volume may be increased along with a loss of cortical bone, but this is in part due to deposition of woven immature collagen fibrils instead of lamellar fibrils. Thus, bone strength suffers despite the increase in mass detected by dual-energy x-ray absorptiometry. Patients undergoing chronic dialysis may have a loss or gain in bone volume depending on bone balance. When the bone balance is positive, osteosclerosis may be observed when osteoblasts are active in depositing new bone, especially woven bone, thus superseding bone resorption. This is rare in the twenty-first century due to improved therapy of secondary hyperparathyroidism.[145]

In the case of negative bone balance, bone loss occurs in cortical and cancellous bone and is more rapid when bone turnover is high. In those cases, bone densitometry will detect osteopenia or osteoporosis.[159,160] The prevalence of osteoporosis in the population with CKD exceeds the prevalence in the general population.[161-163] Osteoporosis is observed in CKD before dialysis is required for ESRD.[164] When bone turnover is high, as in secondary hyperparathyroidism with osteitis fibrosa, bone resorption rates are in excess of bone formation, and osteopenia progressing to osteoporosis may result. When bone turnover is low, although both bone formation rates and bone resorption may be reduced, resorption exceeds bone formation, and loss of bone mass occurs. Thus, osteoporosis may be observed with either high-turnover[164-167] or low-turnover[168] forms of osteodystrophy. When bone resorption exceeds bone formation rates in CKD, positive phosphorus and calcium balance results in the development of hyperphosphatemia and hypercalcemia without an increase in skeletal mineral deposition, but with a stimulation of heterotopic mineralization, especially of the vasculature. The failure of the skeleton to absorb positive phosphate balance in CKD is an important stimulus to heterotopic mineralization and links the skeleton and osteoporosis in CKD to cardiovascular events and mortality.[122]

It is apparent that four forms of osteoporosis associate with the CKD-MBD: high-turnover ROD causing osteoporosis, low-turnover ROD causing osteoporosis, osteoporosis preceding CKD, and osteoporosis due to gonadal hormone deficiency. In patients with osteoporosis and decreased estimated eGFR, it is important to determine the presence of CKD and the state of the CKD-MBD.

Bone Aluminum, Iron, Lanthanum, Bisphosphonate Accumulation

Aluminum, iron, lanthanum,[169] and bisphosphonates accumulate in bone at the mineralization front, at the cement lines, or diffusely. The extent of stainable aluminum at the mineralization front correlates with histologic abnormalities in mineralization. Aluminum deposition is most severe in cases of low-turnover osteomalacia. However, aluminum deposition can be observed in all histologic forms of ROD. In patients in whom an increased aluminum burden develops, bone mineralization and bone turnover progressively decrease. These abnormalities are reversed with removal of the aluminum. Iron also accumulates at the mineralization front and can cause low-turnover forms of ROD and fractures,[170,171] similar to aluminum, although much less is known regarding skeletal iron intoxication than skeletal aluminum intoxication. Lanthanum has been added as a rare earth ion administered to CKD and ESRD patients as a phosphate binder. It is poorly absorbed, and its levels in bone are much lower than aluminum and not clinically relevant.[172] Therapy with lanthanum has not been shown to have long-term toxic effects, and studies suggest skeletal efficacy of lanthanum therapy.[173-175] Eight-year data suggest that the levels of skeletal accumulation remain below those associated with any biologic or toxic effects.[176] Lanthanum disappearance from bone deposits is slow, but not as slow as bisphosphonate disappearance.[172]

Bisphosphonates are drugs used in the treatment of osteoporosis and hypercalcemia.[177,178] There are increasing instances of bisphosphonate use in patients with CKD and ESRD, especially for treatment of VC.[179] Many patients in the multiple bisphosphonate registration trials were retrospectively found to have reduced eGFR.[180,181] Generally, these were elderly women who most likely did not have kidney disease or the CKD-MBD, as they did not have elevated PTH levels. Therefore, there is concern regarding extrapolating data from these trials to patients with osteoporosis and CKD. The nature of the bone remodeling abnormalities in CKD, especially with woven bone formation and mineralization defects, conveys a high level of risk for skeletal deposition of a substance that, once deposited, may not be removed. Such a risk of long-term retention of an active drug inhibiting bone turnover is now being recognized with use of bisphosphonates in osteogenesis imperfecta, and the rare side effect of the drugs in osteonecrosis of the jaw and atypical femoral fractures.[179,182] The US Food and Drug

Administration has added to its bisphosphonate warnings, due to nephrotoxicity of potent bisphosphonates.[177]

Management of Osteoporosis in Chronic Kidney Disease

Recently, prospective studies have shown that measurement of bone mineral density by dual-energy x-ray absorptiometry predicts incident fracture, providing nephrologists with the ability to risk-classify patients for skeletal fragility and targeted antifracture strategies for the first time. Furthermore, an expanding body of literature and anecdotal evidence suggest that pharmacologic agents used to treat osteoporosis in the general population can be safely used in patients with CKD. The KDIGO has updated guidelines for the management of CKD-associated osteoporosis and reviews recent investigations on the effects of antiosteoporotic agents in patients with CKD, including an overview of novel antiosteoporosis agents and the potential challenges related to their use in CKD.[183] This topic is beyond the scope of this chapter, and the reader is referred to recent reviews for an in-depth discussion.[184]

KEY POINTS

- Renal osteodystrophy is highly prevalent in chronic kidney disease (CKD), especially in end-stage renal disease (ESRD). It is characterized by assessing mineralization, turnover, and volume. Osteoporosis can be present in both high- and low-turnover disease but is most prevalent with low-turnover disease. New research suggests that treatment of osteoporosis in CKD until ESRD develops can be similar to its therapy with normal renal function.

Clinical Manifestations

Patients with early-stage CKD are rarely symptomatic due to ROD and its skeletal pathology, but they are usually hypertensive. If the CKD-MBD contributes to hypertension, the pulse pressure may be high due to vascular stiffness and increased pulse wave velocity.[185] However, fracture risk for CKD patients is increased more than 2-fold above age-matched cohorts without CKD.[186,187] Stimulation of VC in the setting of disordered skeletal remodeling is a life-threatening complication of the CKD-MBD.[188,189] VC produces vascular stiffness.[15] Vascular stiffness in CKD causes an increase in systolic blood pressure, a widening of the pulse pressure, and an increase in pulse wave velocity. All of these contribute to cardiac hypertrophy, heart failure, and cardiovascular mortality.[190] However, CKD causes multifactorial direct effects on the heart, contributing to progression through cardiac hypertrophy to heart failure and culminating in cardiovascular mortality. These factors include FGF23, loss of Klotho, and the newly discovered effects of Activin A in CKD.

Heterotopic Mineralization, Calciphylaxis, and Tumoral Calcinosis

Heterotopic tissue calcification may occur in the eyes and manifest as band keratopathy in the sclera or induce an inflammatory response known as the red eye syndrome in the conjunctiva. Calcium deposits are also found in the lungs, leading to restrictive lung disease. Deposits in the myocardium may cause arrhythmias, annular calcifications, valvular calcification, or myocardial dysfunction. Calcification of the kidney may contribute to progression of CKD. Most soft tissue calcifications are attributed to the increased calcium phosphate product contributed to by ROD and excess bone resorption.

The syndrome of calciphylaxis is characterized by VC in the tunica media of peripheral arteries.[191,192] These calcifications induce painful violaceous skin lesions that progress to ischemic necrosis.[193] This syndrome is associated with serious complications and often death.

Tumoral calcinosis is a form of soft tissue calcification that involves the periarticular tissues. Calcium deposits may grow to enormous size and interfere with the function of adjacent joints and organs. Although this type of calcification is usually associated with high calcium phosphate products, its exact pathogenesis is poorly understood. The recent discoveries of three single gene mutations in *FGF23*, *Klotho*, and *GALNT3* causing inherited tumoral calcinosis shed light on the role of hyperphosphatemia in the pathogenesis of tumoral calcinosis.[194-196] The role of GALNT3 in hyperphosphatemia is associated with enzymatic degradation of FGF23.

Bone Pain, Fractures, and Skeletal Deformities

Symptoms of ROD related to the skeleton appear in patients with advanced CKD.[197] Clinical manifestations are preceded, however, by an abnormal biochemical profile that should alert the physician and prompt steps to prevent more severe complications. When symptoms related to the skeleton occur, they are usually insidious, subtle, nonspecific, and slowly progressive.

Bone pain is usually vague, ill-defined, and deep-seated. Bone pain may be diffuse or localized in the lower part of the back, hips, knees, or legs. Weight-bearing and changes in position commonly aggravate bone pain. Bone pain may progress slowly to the degree that patients are completely incapacitated. Bone pain in patients with ESRD usually does not cause physical signs. Local tenderness, however, may be apparent with pressure. Occasionally, pain can occur suddenly at one joint of the lower extremities and mimic acute arthritis or periarthritis not relieved by heat or massage. A sharp chest pain may indicate rib fracture. Spontaneous fractures or fractures after minimal trauma may also occur in vertebrae (crush fractures) and in tubular bones.

Bone pain and bone fractures can be observed in all patients with ESRD independent of the underlying histologic bone disease, especially when osteoporosis is present.[161] However, low-turnover osteomalacia and aluminum-related bone disease are associated with the most severe bone pain and the highest incidence of fractures and incapacity.

Skeletal deformities can be observed in children and adults. Most children with ESRD have growth retardation, and bone deformities may develop from vitamin D deficiency (rickets) or secondary hyperparathyroidism.[138] In rickets, bowing of the long bones is seen, especially the tibiae and femora, with typical genu valgum that becomes more severe with adolescence. Longstanding secondary hyperparathyroidism in children may be responsible for slipped epiphyses secondary to impaired transformation of growth cartilage into regular metaphyseal spongiosa. This complication most commonly affects the hips, becomes obvious in preadolescence, and causes limping but is usually painless. When the radius and ulna are involved, ulnar deviation of the hands and local swelling may occur. In adults, skeletal deformities can be observed in cases of severe osteomalacia or osteoporosis and include lumbar scoliosis, thoracic kyphosis, and recurrent rib fractures.[198]

CONCLUSION

CKD produces a complex syndrome of disrupted systems biology that affects the vasculature, heart, skeleton, muscle, and mineral metabolism and that contributes a major component of its mortality. The advances in our understanding of the CKD-MBD syndrome and its pathogenesis bring into focus the great need for new therapeutics. The 2017 update of clinical practice guidelines by KDIGO[6] demonstrates that our therapies are focused on the late components of the syndrome, and have not improved its mortality in clinical trials (EVOLVE, OPERA, PRIMO, IMPROVE-CKD) despite control of secondary hyperparathyroidism.[127,199-201] Thus, there is great need for discoveries related to therapeutic targets for the CKD-MBD cardiovascular components and thedevelopment of therapeutic agents.

MINERALIZATION

Mineralization of bone is a complex process in which the calcium-phosphate inorganic mineral phase is deposited in relation to the organic protein matrix in a highly ordered fashion. Optimal mineralization requires synthesis of normal matrix at a normal rate by osteoblasts; an adequate supply of calcium and inorganic phosphate (Pi) from the extracellular fluid; an appropriate pH (~7.6) at sites of mineralization; and physiologic amounts of inhibitors of mineralization, notably, elevation in the pyrophosphate/phosphate (PPi/Pi) ratio inhibits mineralized matrix formation. Clinical disorders of mineralization can be attributed to defects at several of these steps, examples of which are shown in Table 62.1.

Mineralization of the skeleton is dependent on a normal calcium x phosphate product. Serum calcium is regulated by $1,25(OH)_2D$ and parathyroid hormone (PTH). $1,25(OH)_2D$ binds the vitamin D receptor (VDR) and promotes calcium absorption predominantly in the duodenum.[2] PTH increases calcium absorption in the distal renal tubule, and both $1,25(OH)_2D$ and PTH stimulate osteoclastic bone resorption to release calcium into the circulation. In the intestine, phosphate from the diet is absorbed passively between cells and transcellularly by the sodium phosphate transporter (NPT) 2b (NPT2b). Phosphate is filtered by the kidney and predominantly resorbed in the proximal renal tubules via the sodium phosphate transporters NPT2a and NPT2c. Fibroblast growth factor 23 (FGF23), produced by osteocytes and osteoblasts, is a major regulator phosphate homeostasis. Although both FGF23 and PTH decrease circulating phosphate by increasing renal phosphate wasting, FGF23 also impairs the production of $1,25(OH)_2D$ by inhibiting the vitamin D 1-alpha-hydroxylase and increasing inactivation of vitamin D metabolites by inducing the 24-hydroxylase.[3]

The precise mechanisms that govern mineralization have yet to be elucidated. It is thought that early mineralization occurs in matrix vesicles that accumulate calcium and Pi, initiating the formation of hydroxyapatite crystals.[4] Phosphatase orphan 1 (PHOSPHO1), a potent phosphohydrolase whose substrates include phosphoethanolamine and phosphocholine, is thought to release phosphate from the membrane phospholipids of matrix vesicles, thus providing phosphate for formation of crystals within matrix vesicles. Ablation of PHOSPHO1 in mice markedly impairs mineralization, supporting an important *in vivo* role for this protein.[5] The earliest calcium-phosphate (Ca-P) mineral phase is comprised of small apatite crystals that are thought to form complexes with phosphoproteins of the organic matrix.[6] The ultimate size and shape of the Ca-P crystals are also influenced by anionic electrolytes in the environment.

The major driving force for mineralization is the concentration of Pi, which, at normal sites of mineralization, is derived predominantly from the plasma. Therefore, control of renal Pi reabsorption is a critical process regulating mineralization. Tissue-nonspecific alkaline phosphatase (TNAP) generates additional Pi to promote mineralization.[7] Loss of function of TNAP results in accumulation of phosphorylated osteopontin, a known inhibitor of matrix mineralization,[8] as well as accumulation of inorganic pyrophosphate (PPi), a potent inhibitor of mineralization, both of which contribute to osteomalacia. Ectonucleoside triphosphate/diphosphohydrolase has also been shown to hydrolyze extracellular diphosphates into monophosphates and Pi. Mutations of this gene impair skeletal mineralization in zebrafish.[9] PPi is generated by osteoblasts and chondrocytes through the action of two enzymes: the ectonucleoside pyrophosphatase phosphodiesterase 1 (ENPP1), which releases PPi from nucleoside triphosphates, and the transmembrane protein ANK, which shuttles PPi between intracellular and extracellular compartments.[10] The specificity of normal bone mineralization is in part explained by the exclusive coexpression of the predominant organic matrix protein, type I collagen, and the enzyme that

TABLE 62.1 Examples of Disorders That Lead to Impaired Mineralization

Disorder	Mechanism
Postoperative hyperparathyroidism	Rate of matrix synthesis exceeds rate of mineralization
Fibrogenesis imperfecta ossium	Defective collagenous matrix
Renal tubular phosphate leak	Phosphate concentration deficient at mineralization sites
Vitamin D deficiency	Insufficient calcium and phosphate
Systemic acidosis	pH inadequate for mineralization
Hypophosphatasia	Excess inhibitors including pyrophosphate

hydrolyzes the inhibitor, PPi. Furthermore, the protein mineralization inhibitor matrix GLA protein is expressed in several tissues, including the growth plate, but not in bone.[11]

The mechanism of defective mineralization varies in disorders associated with osteomalacia and rickets, and biochemical indices such as serum levels of calcium and phosphorus also differ. The relative imbalance in matrix synthesis and its mineralization depend upon the underlying disease mechanism. Estimates from tetracycline labeling indicate that the appositional growth rate in normal bone is about 1 μm/day,[12] and that complete mineralization of osteoid requires approximately 10 to 21 days.[13] Thus, the thickness of the osteoid seam is dependent upon the rate of bone formation and the rate of mineralization. The major histologic criteria for the diagnosis of osteomalacia are an increased osteoid surface and increased osteoid thickness (Fig. 62.1).

The architecture of the cells and matrix in osteomalacic bone is usually normal. Osteocytes, chondrocytes, and osteoblasts all play roles in skeletal mineralization. Osteocytes have been shown to resorb their surrounding mineralized matrix in a PTH/PTH-related protein–dependent fashion, in states of high calcium demand like lactation.[14] Hypomineralized periosteocytic lesions have been also been observed in X-linked hypophosphatemia (XLH).[15] Improvement in serum phosphate and 1,25(OH)$_2$D levels in the mouse model of XLH attenuates these periosteocytic lesions.[16] In addition, there are clear abnormalities in the cellular composition of the rachitic growth plate. Whereas the resting and proliferative zones show normal histologic features (Fig. 62.2), the number of cells per column in the hypertrophic chondrocyte layer is increased, and the cells are irregularly aligned. This is accompanied by widening of the transverse diameter, resulting in characteristic cupping or flaring of the metaphysis. Osteoblast function is impaired in many forms of human rickets and osteomalacia, leading to abnormal matrix formation; notably, the hydroxylation of certain collagen lysyl residues is increased in vitamin D–deficient bone, as well as in other experimental hypocalcemic states.[17]

KEY POINTS

- Calcium and phosphate balance are critical for normal skeletal mineralization. Hormones including vitamin D, parathyroid hormone, and fibroblast growth factor 23 regulate calcium and phosphate homeostasis.

CLINICAL FEATURES OF RICKETS AND OSTEOMALACIA

The clinical manifestations of rickets are mainly related to skeletal pain and deformity, slippage of epiphyses, disturbances in growth,

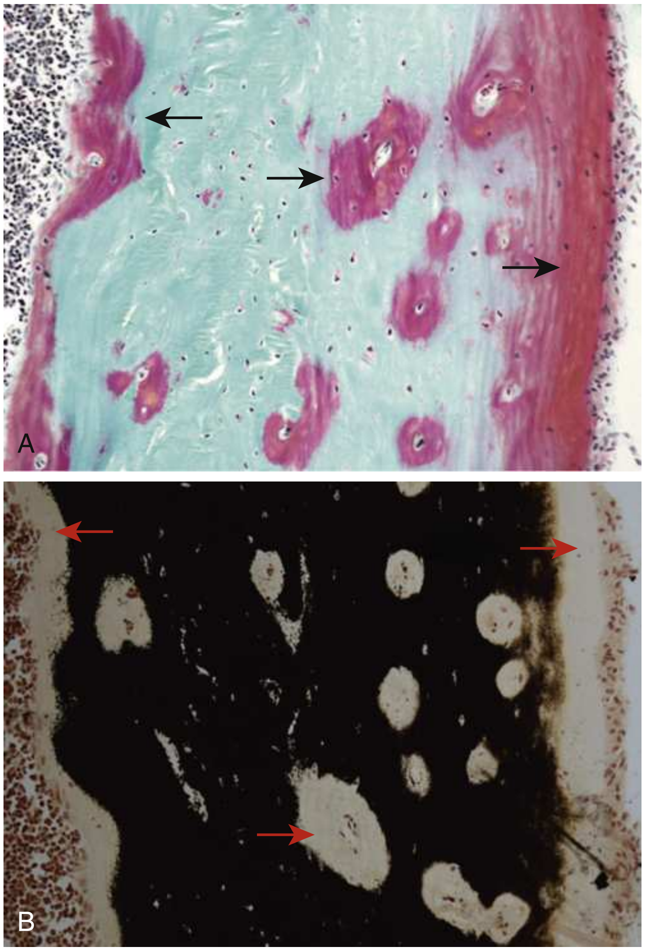

Fig. 62.1 Osteomalacia in the cortical bone of a Hyp mouse, the mouse model of X-linked hypophosphatemia. **A,** Trichrome stain, osteoid in red, mineralized bone in green. **B,** Von Kossa stain, osteoid in beige, mineralized bone in black. Osteoid is noted by arrows, pointing to the periosteal and endosteal cortical surfaces and periosteocytic halos.

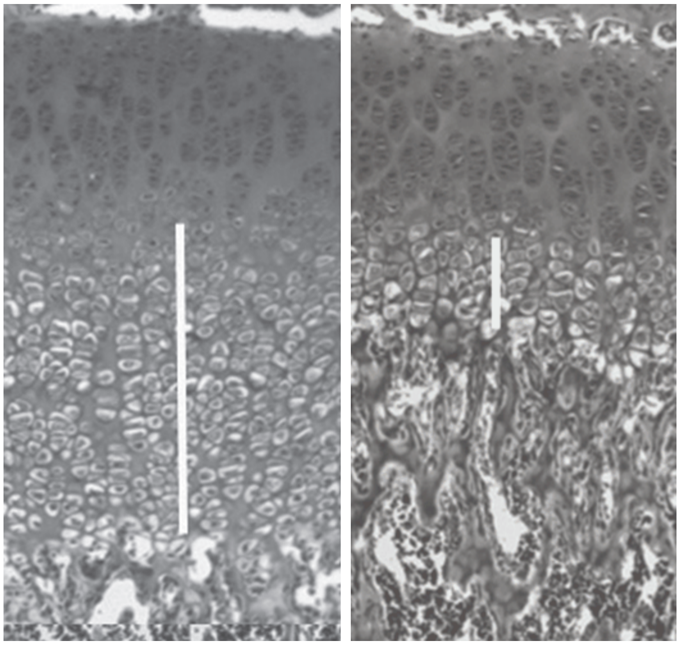

Fig. 62.2 Histology of the growth plate in a mouse model of renal phosphate wasting *(left)* and control normal mouse *(right)*. The extent of the hypertrophic chondrocyte layer is indicated by the white bar.

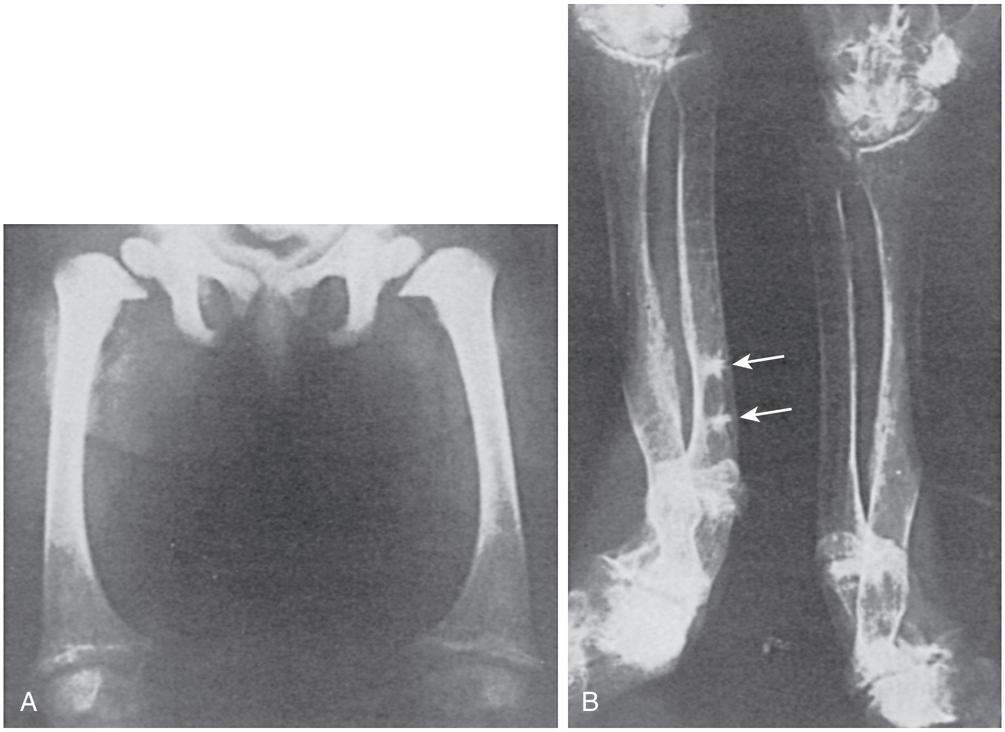

Fig. 62.3 A, Rickets in a child with Fanconi syndrome showing typical cupping of distal femoral epiphyses. B, Osteomalacia in an 80-year-old woman who had a history compatible with hypophosphatemic rickets dating to early childhood. Note multiple pseudofractures *(arrows)*.

and fracture of the osteomalacic bones. Hypocalcemia, when it occurs, may be symptomatic. Depending on the degree of hypophosphatemia, muscular weakness and hypotonia may be prominent features. Dent and Stamp have indicated several factors that underlie the clinical manifestations of rickets and osteomalacia.[18] Rickets affects predominantly rapidly growing parts of the skeleton: endochondral bone is more affected than intramembranous bone, presumably because of the more rapid growth of the former. Because the rate of growth of specific bones differs at different stages of development, the time when rickets is active determines the clinical expression. For example, the skull is growing rapidly at birth; therefore, craniotabes is a manifestation of congenital rickets. During the first year, the upper limbs and rib cage grow rapidly; thus, abnormalities at these sites are prominent, for example, rachitic rosary. Because the growth rate of the distal ulnar epiphysis is greater than that of the distal radial epiphysis, rickets is most prominent at the ulna. Similarly, proximal and distal ends of bones do not grow at the same rate; thus, rickets affects the most rapidly growing region. Rickets that occurs at the time of the pubertal growth spurt produces dramatic disturbances and results in knock-knee. Deformities that occur before the age of 4 years correct themselves if the rickets is successfully treated; if rickets persists to a later age, the deformities are permanent. Adult manifestations of osteomalacia, such as Looser's zones, are seen in young children only when the rickets is very severe. In some forms of rickets, the radiologic changes include those of secondary hyperparathyroidism (subperiosteal resorption, most commonly at the metaphyses).

In infants and young children with severe rickets, listlessness and irritability are common. In infants, hypophosphatemic myopathy is observed and may be accompanied by hypotonia. In older children and adults, the weakness may present as a proximal myopathy. Other findings in infants include parietal flattening or frontal bossing, softening of the calvarium (craniotabes), and widening of the sutures. The expanded growth plates may be evident clinically as a rachitic rosary at the sternocostal junction. Indentation or "bowing" of the lower ribs at the site of attachment of the diaphragm is known as Harrison's groove or sulcus. Pelvic deformities also occur, and the skeleton is more prone to fractures. Dental eruption may be delayed, and enamel defects are common.

Osteomalacia in adults may be difficult to diagnose on clinical grounds alone. Diffuse skeletal pain and muscular weakness may be present. Fractures occur in the ribs, vertebral bodies, and long bones, and progressive deformities may result from impaired fracture healing. Symmetric polyarthralgias resembling those of rheumatoid arthritis or polymyalgia rheumatica are occasionally observed. Proximal muscular weakness, often associated with a waddling gait and hypotonia, is thought to be a consequence of hypophosphatemia. The molecular basis remains elusive, with no difference observed in the relative concentrations of skeletal muscle phosphocreatine, adenosine triphosphate, or Pi estimated by phosphorus nuclear magnetic resonance (MR) spectroscopy.[19] Thus, the etiology of the neuromuscular features of osteomalacia is not clearly defined; however, therapy of the underlying disorder, such as vitamin D in nutritional osteomalacia, alkalinization in acidosis, and phosphate repletion in hypophosphatemic osteomalacia, results in resolution of these features.

RADIOLOGIC FEATURES

Radiologic features of rickets and osteomalacia reflect the histopathologic changes. In rickets, the epiphyseal growth plate is widened, with a cupped metaphysis and an ill-defined diaphyseal border because of decreased mineralization (Fig. 62.3). The trabecular pattern of the metaphyses is poorly defined, and the cortices of the diaphyses may be thinned and bowed.

Osteomalacia is caused by decreased mineralization; therefore, is associated with a decrease in bone density, loss of trabecular patterning, and variable degrees of thinning of the cortices. In some patients, radiologic changes are indistinguishable from those seen in osteoporosis. The characteristic finding that specifically suggests osteomalacia is the presence of radiolucent bands, ranging from a few millimeters to several centimeters in length, usually oriented perpendicularly to the surface of the bone, known as pseudofractures or Looser's zones (Fig. 62.4). They occur symmetrically and are common at the inner aspects of the femur near the femoral neck, in the pelvis, in the outer edge of the scapula, in the upper fibula, and in the metatarsals. Pseudofractures are most often seen at sites where major arteries cross the bones, and arteriography in some cases suggests that the origins of the pseudofractures correspond to the location of major arteries, like the pseudofractures in the iliac crest observed in Fig. 62.4. Local trauma, whether related to arterial pulsation or other factors, such as weight-bearing stress, is likely responsible for the symmetry of the lesions and their predilection for the described sites. The histology of Looser's zones is that of premalacic lamellar bone, some of which is surrounded by lamellar osteoid at the edge of the defect.[20] In addition, there are foci of woven bone with variable mineralization, accounting for the lower radiologic density of the pseudofracture relative to the surrounding bone. Subperiosteal erosions along the cortices may be seen when secondary hyperparathyroidism is present. Widening (or pseudowidening) of the sacroiliac joints with hazy margins has also been observed.

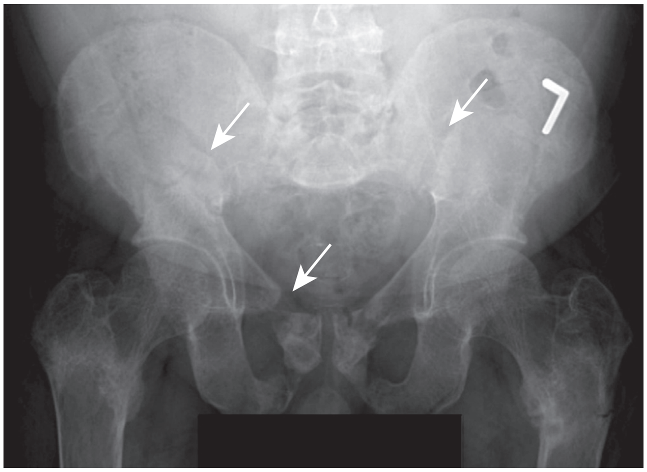

Fig. 62.4 Radiograph of the pelvis and proximal femora in an adult with tumor-induced osteomalacia. Numerous pseudofractures (Looser's zones) are observed. Arrows point to those in the superior pubic ramus and iliac crests. A left femoral fracture and right femoral stress fracture are also seen.

In some patients with osteomalacia, increased radiopacity of bones may be observed.[21] This is seen particularly in patients with renal tubular phosphate leaks, but not in vitamin D deficiency or generalized defects in proximal renal tubular reabsorption (Fig. 62.5). Despite the increase in mass of bone per unit volume, microscopically the trabeculae are covered with abnormally thickened osteoid seams typical of osteomalacia. Similar findings may be noted in patients with chronic kidney disease. The reason for the hyperostosis is unknown; however, the bone is architecturally abnormal and predisposed to low-trauma fractures. In patients with XLH, an additional finding has been the presence of a generalized involvement of the entheses, with mineralization of tendon and ligament insertions.[22] The absence of inflammatory cells, as well as other clinical features, differentiates this disorder from degenerative joint disease and the seronegative spondyloarthropathies.

A comprehensive classification of rickets and osteomalacia is shown in Table 62.2.

KEY POINTS

- Clinical and radiologic findings in children with rickets are often associated with impaired growth and growth plate maturation.
- Osteomalacia in adults can be associated with nonspecific clinical symptoms like skeletal pain, muscle weakness, and fractures.

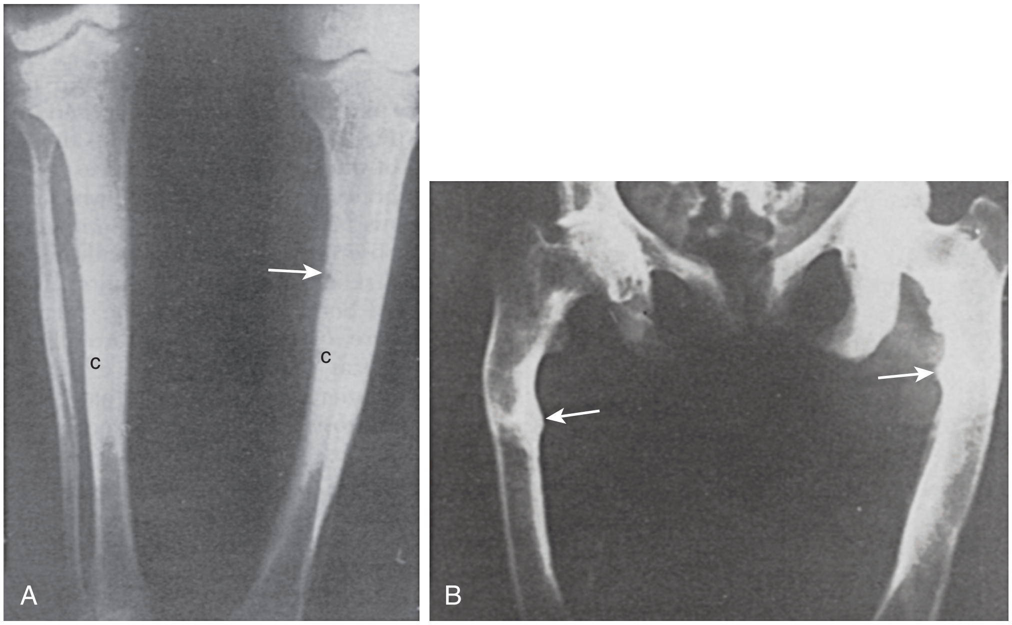

Fig. 62.5 Increased bone mass in patients with osteomalacia. **A,** Radiographs of tibiae of a 15-year-old boy with X-linked hypophosphatemia. Note the thick tibial cortex *(c)* and Looser's zone *(arrow).* **B,** Radiograph of pelvis and femora of a 38-year-old woman with hypophosphatemia present since childhood. TABLE 62.2 Classification of Rickets and Osteomalacia

I. Nutritional
- A. Vitamin D deficiency
  - 1. Dietary deficiency
  - 2. Deficient endogenous synthesis
- B. Calcium deficiency
  - 1. Dietary deficiency

II. Gastrointestinal diseases
- A. Intestinal
  - 1. Small intestine diseases with malabsorption
  - 2. Partial or total gastrectomy
  - 3. Obesity and Intestinal bypass
- B. Hepatobiliary
  - 1. Cirrhosis
  - 2. Biliary fistula
  - 3. Biliary atresia
- C. Pancreatic
  - 1. Chronic pancreatic insufficiency

III. Disorders of vitamin D metabolism
- A. Hereditary
  - 1. Isolated 25-hydroxyvitamin D deficiency
  - 2. Pseudovitamin D–deficiency rickets
  - 3. Hereditary vitamin D–resistant rickets
  - 4. CYP3A4 gain-of-function mutations
  - 5. FGF23 excess
- B. Acquired
  - 1. Hypoparathyroidism
  - 2. Anticonvulsants
  - 3. Renal insufficiency
  - 4. FGF23 excess

IV. Hypophosphatemia
- A. FGF23-dependent
  - 1. Genetic
    - a. XLH, ADHR, ARHR1, ARHR2
    - b. FAM20C mutation (Raine syndrome)
    - c. Fibrous dysplasia
  - 2. Acquired
    - b. Tumor-induced osteomalacia
- B. Non–FGF23-dependent
  - 1. Genetic
    - a. Hereditary hypophosphatemic rickets with hypercalciuria
  - 2. Dietary
    - a. Low phosphate intake with gastrointestinal disease
    - b. Alcohol use disorder
  - 3. Hyperparathyroidism

V. Miscellaneous causes of impaired mineralization
- A. Acidosis
  - 1. Distal renal tubular acidosis
- B. General renal tubular disorders (Fanconi syndrome)
  - 1. Primary renal
  - 2. Systemic disorder with associated tubular dysfunction
- C. Chronic kidney disease
- D. Aluminum, fluoride, and heavy metal intoxication
- E. Hypophosphatasia
- F.Osteopetrosis
- G. Fibrogenesis imperfecta ossium

NUTRITIONAL OSTEOMALACIA AND RICKETS

In seventeenth century Scotland and England, the association of poverty and malnutrition with the occurrence of infantile rickets was vividly documented. The link between rickets, dietary vitamin D deficiency, and correction of vitamin D deficiency by solar radiation was established in 1923 by the work of the Vienna Council. Following this discovery, fortification of certain foods with vitamin D reduced the incidence of nutritional rickets in Europe and the United States to negligible levels, so that by the 1940s vitamin D deficiency was no longer regarded as an important cause of osteomalacia and rickets.

Studies in Glasgow and London documented the reappearance of nutritional osteomalacia and rickets as a public health problem in Britain.[23,24] Since the 1950s, the population at risk primarily involved immigrants from East Asia, most commonly neonates, infants, and adolescents during pubertal growth.[25] Multiple factors have been implicated in this, including insufficient intake of calcium and vitamin D, skin pigmentation (which decreases cutaneous synthesis of vitamin D), genetic factors, and social customs (such as avoidance of sun exposure and consumption of a diet high in phytate that interferes with calcium absorption).[26,27] Based on studies demonstrating that hyperparathyroidism accelerates the rate of inactivation of vitamin D in the liver,[28] calcium deficiency leading to secondary hyperparathyroidism in this population can also exacerbate vitamin D deficiency.

Analogous increases in nutritional rickets have been reported in North America. Studies from the Mayo clinic demonstrate a dramatic increase in nutritional rickets in Olmsted county from 2.2 to 24.1 per 100,000 children between 1980 and 2000.[29] Associated risk factors included breastfeeding, low birth weight, and African ancestry. Low–birth weight infants are particularly at risk for rickets, with the reported incidence ranging from 13% to 32%. The condition should be detected early because prompt nutritional supplementation is required. Infants of vitamin D–deficient mothers are at greatest risk for neonatal rickets, which can be averted by maternal vitamin D supplementation during pregnancy.[30] Special consideration should be given to screening for vitamin D deficiency during pregnancy in women whose social and dietary history reveal inadequate sun exposure and food sources of vitamin D. Infants who are entirely breastfed and have inadequate exposure to sunlight also are at risk for rickets because the amount of vitamin D and 25(OH)D in human milk is inadequate.[31]

Vitamin D sources include dietary supplementation with ergocalciferol (vitamin D2), a plant-based provitamin, and cholecalciferol (vitamin D3), which is produced in skin by the action of ultraviolet light on 7-dehydrocholesterol. Because most foods (with the exception of wild fatty fish) contain only small amounts of vitamin D3, individuals must rely on either adequate sunlight exposure or dietary supplements to avoid vitamin D deficiency. There is marked seasonal variation in plasma 25(OH)D, independent of age and sex.[32] These variations parallel changes in duration and intensity of sun exposure, with higher values in late summer months in the northern hemisphere. In the United States, plasma 25(OH)D levels are almost twice as high in American women of European ancestry than in those of African ancestry during winter months, and the increment during summer months is also greater.[33] Plasma 25(OH)D and PTH levels are inversely correlated, implying that the changes in circulating 25(OH)D are physiologically significant.[34] Thus, adequate vitamin D supplementation is essential when exposure to sunlight is marginal.

In addition to housebound and elderly subjects, those on vegetarian or fat-free diets[35,36] are susceptible to vitamin D deficiency. Vitamin D requirements are greater in the elderly than in young adults. This difference is attributed to an age-related decline in dermal production of 7-dehydrocholesterol, the precursor for vitamin D3,[37] diminished renal production of 1,25(OH)$_2$D, and diminished intestinal absorption of calcium caused by lower levels of the VDR in the intestine.[38] Other contributing factors include previous gastric surgery and occult malabsorption, in addition to altered vitamin D metabolism. How much vitamin D supplementation is necessary varies widely based on dietary factors, solar exposure, and comorbid conditions including medications. Guidelines from the US Institute of Medicine[39] and the Endocrine Society[40] differ. The former suggests ingestion of approximately 800 IU of vitamin D per day in healthy adults and a level of 25-hydroxyvitamin D greater than 20 ng/mL (50 nmol), whereas the latter favors a level great than 30 mg/mL (75 nmol). The major limitation of the recommendations of both these guidelines with respect to skeletal health is the absence of consideration of comorbid conditions and calcium intake, as calcium deficiency *per se* can result in rickets and osteomalacia.[41] Serum 1,25(OH)$_2$D is not a reliable indicator of vitamin D status because values may be normal in individuals with vitamin D deficiency.[42]

Nutritional rickets caused by calcium deficiency was first reported in 1978 by Pettifor and coworkers,[43] who described findings in children in rural South Africa. These children had adequate sunlight exposure, normal calcium absorption, and normal serum 25(OH)D and serum 1,25(OH)$_2$D values. The biochemical and radiographic changes of rickets were entirely corrected by treatment with calcium alone. In a prospective, randomized, double-blind study of 123 Nigerian children with nutritional rickets, treatment with calcium alone or calcium and vitamin D together was more effective than treatment with vitamin D alone.[44] Calcium deficiency is also prevalent in children in North America and can contribute to nutritional rickets. Review of the records of 43 infants and toddlers who presented with rickets in New Haven, Connecticut (86% of whom were of African, Hispanic, or Middle Eastern ancestry, and more than 93% of whom had been breastfed) revealed serum 25(OH)D levels less than 15 ng/mL in only 22%. However, 86% of those with a food history had been weaned to diets with minimal calcium content.[45]

GASTROINTESTINAL DISEASES

Malabsorption associated with diseases of the small intestine, hepatobiliary tree, and pancreas is the most common cause of severe vitamin D deficiency in the United States. Disorders of the small intestine that cause malabsorption of vitamin D and resultant osteomalacia include celiac disease, Crohn's disease, scleroderma, multiple jejunal diverticula, and blind-loop syndrome. Impaired absorption of calcium *per se* also contributes to the development of rickets and osteomalacia.[41] Rickets occurs in infants and children with cholestatic liver disease[46] and biliary atresia because of markedly impaired vitamin D absorption.[47] In adults, osteomalacia is most common in patients with cholestasis (particularly primary biliary cirrhosis), but is also observed in patients with alcoholic liver disease and other forms of cirrhosis. In most patients, the low serum levels of 25(OH)D are attributable to impaired intestinal absorption of vitamin D; however, reduced exposure to ultraviolet light and reduced dietary intake also contribute.[48] Treatment with vitamin D metabolites can heal hepatic osteomalacia.

Other populations at risk for development of nutritional osteomalacia are the morbidly obese and those who have undergone bariatric surgery for treatment of severe obesity.[49-52] The etiology for the osteomalacia is thought to be as a result of the presence of vitamin D deficiency before surgery combined with postoperative impairment in intestinal calcium and vitamin D absorption. The low vitamin D levels lead to hypocalcemia, hypophosphatemia, and osteomalacia. Because adequate mixing of food with bile acids and pancreatic enzymes in the small intestine is needed for vitamin D absorption, patients who undergo Roux-en-Y gastric bypass or biliopancreatic diversion/duodenal switch are particularly at risk for postoperative vitamin D deficiency.[53] In one series, iliac bone biopsies from patients who had undergone intestinal bypass revealed the presence of osteomalacia in six of 21 patients.[52] Treatment with vitamin D2 (36,000 IU/day), as well as supplemental calcium (27 mmol/day), was required to promote a more positive calcium balance in some individuals.[50] Patients who undergo sleeve gastrectomy are at risk for nutritional osteomalacia because of inadequate dietary intake of vitamin D and calcium.[54,55] An increased frequency of osteomalacia is also observed postgastrectomy as well, the severity of the mineralization defect being positively correlated with serum 25(OH)D, but not serum 1,25(OH)$_2$D, levels.[56]

DISORDERS OF VITAMIN D METABOLISM

Rickets or osteomalacia can be caused by gene mutations in enzymes responsible for vitamin D metabolism (see Chapter 58). Isolated deficiency of 25(OH)D is a rare autosomal recessive disorder caused by impaired hepatic production of 25(OH)D. The disease is characterized by low serum 25(OH)D, normal serum 1,25(OH)$_2$D, hypocalcemia, increases in serum alkaline phosphatase, secondary hyperparathyroidism, and early onset of rickets. Homozygous L99P and K242N inactivating mutations of CYP2R1 were found to be the cause of 25(OH)D deficiency and rickets in Nigerian children with this disorder.[57] These findings provide evidence that CYP2R1 is the key enzyme catalyzing the conversion of vitamin D to 25-hydroxyvitamin D.

Pseudovitamin D–deficiency rickets is an autosomal recessive disorder caused by impaired production of 1,25(OH)$_2$D. The disease is caused by mutations of the *CYP27B1* gene that encodes the 25(OH) D 1-alpha-hydroxylase, the mitochondrial enzyme that is responsible for conversion of 25(OH)D to 1,25(OH)$_2$D.[58-60] Affected individuals appear normal at birth and develop the clinical and biochemical changes of rickets during the first year of life. Hypocalcemia, hypophosphatemia, elevated serum PTH, and elevated serum alkaline phosphatase are consistent findings. The diagnosis is made by genetic analyses and/or demonstration of a normal serum 25(OH)D and low, or undetectable, serum 1,25(OH)$_2$D in a patient with rickets who responds to physiologic doses of 1,25(OH)$_2$D3.

Hereditary vitamin D–resistant rickets is a rare inherited disorder characterized by resistance of target organs to 1,25(OH)$_2$D. The disease is caused by mutations of the *VDR* gene,[61] is transmitted as an autosomal recessive trait, and is often associated with consanguineous parentage. Onset of symptoms can occur at any age from infancy to adolescence. Patients exhibit hypocalcemia, hypophosphatemia, elevation of serum alkaline phosphatase and PTH, normal or increased serum 25(OH)D, and marked elevation of serum 1,25(OH)$_2$D. Patients may also develop alopecia. Because the pathophysiologic abnormality underlying this disorder is a receptor defect, no treatment has been uniformly successful. Therapeutic responses to pharmacologic doses of vitamin D metabolites and oral calcium supplements vary. Because the main physiologic effect of 1,25(OH)$_2$D is to promote intestinal calcium absorption, treatment with parenteral calcium infusions, circumventing the intestinal resistance to 1,25-dihydroxyvitamin D, can normalize the biochemical abnormalities and lead to clinical and radiologic remission of the osteomalacic lesions.[62]

The molecular basis for a novel form of vitamin D–resistant rickets was reported to be gain-of-function mutations in CYP3A4, a liver cytochrome P450 enzyme. Although this enzyme is thought to play a minor role in normal vitamin D physiology, induction of CYP3A4 underlies the accelerated metabolism of vitamin D observed with several pharmacological agents. The mutation in the substrate recognition site of CYP3A4 seen in affected individuals increases the rate of 1,25-dihydroxyvitamin D inactivation 10-fold versus wild-type CYP3A4. Affected individuals with this disorder have low serum calcium, phosphate, 25(OH)D, and 1,25$(OH)_2$D levels, with secondary hyperparathyroidism. Because this condition leads to accelerated catabolism of 25(OH)D and 1,25$(OH)_2$D, affected patients are treated with high doses of vitamin D or calcitriol.[63]

Hypoparathyroidism is a rare cause of osteomalacia.[64,65] The skeletal disease is attributed to a decrease in 1,25$(OH)_2$D synthesis owing to of lack of PTH and impaired PTH-mediated bone resorption and renal calcium reabsorption, all of which lead to hypocalcemia. Thus, appropriate therapy for hypoparathyroidism should prevent the mineralization defect. Osteomalacia occurs infrequently in pseudohypoparathyroidism, attributed to decreased 1,25$(OH)_2$D, a consequence of impaired renal response to PTH-induced formation of cyclic adenosine monophosphate, as well as hypocalcemia.[66,67] These parathyroid-related disorders are discussed in greater detail in Chapters 52 and 57.

KEY POINTS

- Nutritional rickets can result from inadequate dietary calcium or vitamin D intake.

HYPOPHOSPHATEMIA

FGF23-Mediated Hypophosphatemia

Impaired tubular reabsorption of phosphate is the underlying pathogenesis of hypophosphatemia in many disorders. In 1937, Albright and coworkers reported their studies of a 16-year-old boy with longstanding rickets in whom standard doses of vitamin D failed to produce clinical improvement.[68] Healing of the skeletal disease observed after administration of extremely high doses of vitamin D introduced the concept of "vitamin D resistance" in certain types of rickets. Subsequently, vitamin D–resistant rickets has been classified into several clinical and biochemical subtypes, the most common of which is XLH, characterized by elevated levels of FGF23 that result in renal phosphate wasting and inhibition of the vitamin D 1-alpha-hydroxylase, thus impairing production of 1,25$(OH)_2$D.[69] Affected individuals have hypophosphatemia, low renal resorption of phosphate, inappropriately normal 1,25$(OH)_2$D levels (because hypophosphatemia normally increases 1,25$(OH)_2$D), and modest elevations in serum PTH. Children usually present with clinical and radiographic evidence of rickets, growth retardation, and dental caries. In adults, the clinical course is often complicated by osteoarthritis and mineralization of the tendon-bone insertion sites (enthesopathy).[22] XLH is traditionally treated with a combination oral phosphate and 1,25$(OH)_2$D (calcitriol). More recently, a novel anti-FGF23 blocking antibody (burosumab) was approved for the treatment of children and adults with XLH. While antibody treatment is able to increase serum phosphate levels into the low normal range without increasing serum PTH levels,[70] no therapy has been shown to normalize growth and skeletal mineralization.[71,72]

Positional cloning used to identify the molecular basis for XLH[73] revealed a mutation in the *PHEX* gene, which is structurally similar to genes encoding a group of membrane-bound metalloendopeptidases.[74] It is still unclear how the mutations in this gene lead to increased levels of FGF23.

Autosomal dominant hypophosphatemic rickets (ADHR) is also characterized by isolated renal tubular phosphate wasting and inappropriately normal plasma 1,25$(OH)_2$D levels. Positional cloning identified *FGF23* as the gene mutated in ADHR.[75] These mutations, localized to a subtilisin-like proprotein convertase cleavage site, decrease inactivation of FGF23, thereby leading to elevated circulating levels, which result in renal phosphate wasting. In contrast to XLH, ADHR displays variable and incomplete penetrance and may not present until adolescence/adulthood. Iron deficiency increases FGF23 mRNA expression; thus, iron deficiency can lead to hypophosphatemia in normal individuals and unmask ADHR.[76] Treatment of iron deficiency in patients with ADHR has been shown to normalize serum FGF23 and phosphate levels.[77]

Two forms of autosomal recessive hypophosphatemic rickets (ARHR) have been described. The genetic basis for ARHR1 is a mutation in dentin matrix protein 1 (DMP1), which, like FGF23, is expressed in osteocytes. The clinical features are similar to those seen in XLH, including hypophosphatemia, inappropriately normal or low 1,25-dihydroxyvitamin D, and high circulating FGF23.[78] ARHR2 is secondary to mutations in ectonucleotide pyrophosphatase/phosphodiesterase1 (ENPP1), which cleaves adenosine triphosphate to release the mineralization inhibitor PPi. Clinical characteristics are similar to ADHR1; however, FGF23 levels are not always elevated. Loss-of-function mutations of ENPP1 are the molecular basis for generalized arterial calcification of infancy, an often fatal disorder.[79] Mutations in FAM20c, a kinase that can phosphorylate FGF23, osteopontin and DMP1, have been associated with an FGF23-dependent hypophosphatemic syndrome characterized by dental abnormalities and ectopic mineralization.[80]

Dent and Gertner also described three patients with fibrous dysplasia with hypophosphatemic osteomalacia or rickets.[81] Subsequent investigations revealed that dysplastic tissue produces FGF23, implicating this hormone in the pathogenesis of the renal phosphate leak.[82] Treatment of these and other rare inherited disorders of phosphate homeostasis are discussed in Chapter 53.

Tumor-induced osteomalacia is an acquired hypophosphatemic syndrome secondary to tumor secretion of phosphaturic factors, including FGF23. In 1959, Prader and coworkers described the case of an 11-year-old girl who, over the course of a year, developed severe symptomatic rickets accompanied by hypophosphatemia, renal phosphate wasting, and mild hypocalcemia.[83] The child was found to have a large tumor that was pathologically diagnosed as a reparative giant cell granuloma of a rib. Following excision of the tumor, the rickets healed without any specific therapy. It was postulated that the tumor may have produced a "rachitogenic substance." Since that time, numerous patients have been described with tumor-induced osteomalacia. One review reported that, of 72 tumors, 40 were localized to bone and 31 to soft tissues; two-thirds of the tumors occurred in the extremities.[84] More than one-third of the tumors were classified as vascular tumors, and half of these were hemangiopericytomas. All of the tumors exhibited prominent vascularity, multinucleated giant cells, and primitive stromal cells. Ten of the tumors were classified as malignant. Although most neoplasms associated with this syndrome are of mesenchymal origin, cases associated with prostate carcinoma and pheochromocytoma have been reported. In most of the reported cases, the removal of the tumor results in clinical cure of the osteomalacia or rickets; however, the tumors are usually small and often are not identified until years after development of clinical osteomalacia. Recurrence of the tumor or inadequate removal of the malignancy may prevent a complete clinical response.

Patients with tumor-induced osteomalacia exhibit hypophosphatemia, renal phosphate wasting, and normal serum calcium levels. Serum PTH levels are variable. Tumors that have been isolated express high levels of FGF23 mRNA,[85] and many have a fibronectin:FGFR1 or fibronectin:FGF1 fusion thought to be pathogenic in the increased FGF23 production.[86] Whereas other phosphaturic factors have been found in these tumors, normalization of circulating FGF23 is seen after removal of the tumor and correlates with resolution of the hypophosphatemia. As in XLH, inappropriately low levels of serum 1,25$(OH)_2$D are observed owing to expression of FGF23,[85] and tumor resection may result in a dramatic increase in 1,25$(OH)_2D$, resulting in transient hypercalcemia. Tumors secreting phosphaturic factors may be small and in obscure locations, making tumor localization challenging. The ^{68}Ga-DOTATATE positron emission tomography (PET)/computed tomography (CT) scan is the most sensitive and specific for localization of these tumors.[87] Other imaging modalities used include octreoscan–single-photon emission CT/CT, (^{18}F)-fluorodeoxyglucose–PET/CT, and 3T magnetic resonance imaging (MRI).[87,88] If the tumor secrets a high amount FGF23, venous sampling may be used for tumor localization.[88] If the tumor cannot be localized or resected, affected individuals, like those with hypophosphatemic rickets, are traditionally treated with combination oral phosphate and calcitriol therapy. The phosphate in oral supplements binds serum calcium, resulting in a transient decrease in serum ionized calcium levels and rise in serum PTH levels.[89] The calcium-sensing receptor agonist cinacalcet has been used to treat patients with tumor-induced osteomalacia or hypophosphatemic rickets as adjunctive therapy to improve hypophosphatemia and prevent hyperparathyroidism.[89,90] The anti-FGF23 antibody has recently been approved as a therapy for tumor-induced osteomalacia but has not been shown to cure the osteomalacia.

KEY POINTS

- Genetic and acquired disorders characterized by high serum levels of fibroblast growth factor 23 lead to hypophosphatemia, and thus rickets and osteomalacia.

Non–FGF23-mediated Hypophosphatemia

A mutation in the phosphate transporter SLC34A3 (NptIIc) is the genetic basis for hereditary hypophosphatemic rickets with hypercalciuria. Hypercalciuria is secondary to increased 1,25$(OH)_2D$, which leads to increased intestinal calcium absorption. This hypercalciuria and low serum FGF23 levels distinguish it from the FGF23-related hypophosphatemic rickets.[91] Similarly, homozygous mutations in SLC34A1 (NptIIa) are associated with hypophosphatemic rickets and Fanconi syndrome.[92]

It is difficult to produce selective deficiency of phosphorus by dietary means alone because most foods contain this element in concentrations that are sufficient to prevent hypophosphatemia and skeletal disease. Hypophosphatemia is seen in both chronic and acute alcohol use disorder.[93,94] Bone densitometry and tetracycline-labeled bone biopsies obtained from patients with chronic alcohol use disorder have revealed changes consistent with mixtures of osteoporosis, osteomalacia, and osteitis fibrosa.[95] Multiple factors, including hypomagnesemia, metabolic alkalosis or acidosis, and renal tubular phosphate wasting, contribute to the hypophosphatemia and skeletal disease.

In individuals with primary hyperparathyroidism who have excessive bone resorption and high rates of bone formation, thick osteoid seams may be seen because the rate of bone formation exceeds that of mineralization. This may present clinically as hungry bone syndrome following surgical cure of hyperparathyroidism. However, frank vitamin D deficiency and osteomalacia may coexist with primary hyperparathyroidism because hyperparathyroidism accelerates the rate of vitamin D catabolism.[28]

MISCELLANEOUS CAUSES OF IMPAIRED MINERALIZATION

Acidosis

The mechanism of bone loss and the mineralization defects seen with acidosis are complex and not completely understood. Based on normal subjects in whom metabolic acidosis is induced, it has been proposed that excess retained hydrogen ion is balanced by bone buffering and loss of skeletally derived calcium in the urine.[96] Because the hypercalciuria and increased bone resorption that accompany most acidotic states do not directly result in osteomalacia, other mechanisms must be invoked to explain the occurrence of clinically significant skeletal mineralization defects. Osteoclasts function optimally at a pH of approximately 6.9 and are inactive at a pH greater than 7.3[97]; thus, chronic acidosis may activate the vacuolar hydrogen ion pumps in osteoclasts. In addition, voltage-gated proton channels in osteoclasts can sense changes in pH.[98] As a consequence, calcium release from bone induced by acidosis may be caused by increased osteoclast activity. In parallel, metabolic acidosis inhibits the function of osteoblasts: in osteoblast culture systems, lowering pH to 6.9 decreases formation of mineralized nodules. Although acidosis has been shown to increase renal phosphate wasting, the role of phosphaturic hormones in this process has not been established.[99]

Rickets and osteomalacia secondary to acidosis are most frequently a complication of inherited distal renal tubular acidosis (RTA).[100] Distal or type I RTA is characterized by impaired secretion of hydrogen ions from the distal nephron, resulting in metabolic acidosis, nephrocalcinosis, hypokalemia, rickets, and osteomalacia. Distal RTA can be attributed to genetic defects; systemic disease including hyperparathyroidism, sickle cell disease, and autoimmune disorders; and drugs including lithium, foscarnet, and amphotericin B. Autosomal dominant distal RTA is caused by mutations in the *SLC4A1* gene that encodes a chloride-bicarbonate exchanger.[101] Rarely, mutations in the *SLC4A1* gene occur in recessive RTA as well.

Autosomal recessive distal RTA can be caused by homozygous mutations in the *ATP6VB1* or *ATP6V0A4* genes, which encode the b1 and a4 subunits of the collecting duct apical proton pump vacuolar H^+/ATPase, respectively, and may be associated with progressive bilateral sensorineural hearing loss.[102] Homozygous mutations in the FOXI1 transcription factor have been shown to result in a similar phenotype.[103] Mutations in WDR72 have also been implicated in the pathogenesis of autosomal recessive distal RTA.[104]

Autosomal dominant RTA is usually diagnosed in adults who present with nephrolithiasis and acidosis. Osteomalacia occurs infrequently. In contrast, autosomal recessive RTA presents in infancy or early childhood and is often accompanied by rickets. Healing of the skeletal disease is achieved by correcting acidosis with sodium bicarbonate (5–10 g/day). The response may be enhanced by the addition of vitamin D or 1,25$(OH)_2D3$. Occasionally, vitamin D toxicity can develop; therefore, patients must be monitored carefully.

Another form of inherited mixed distal/proximal RTA, caused by mutations carbonic anhydrase II (CAII), is associated with osteopetrosis and cerebral calcifications.[105,106] The osteopetrosis is as a result of impaired osteoclast function because CAII deficiency impairs the acidification required for bone resorption. It is of interest that bone marrow transplantation does not affect the acidosis, but reverses the osteopetrosis because osteoclasts are of hematopoietic origin.[107]

Osteomalacia may be a complication of the acidosis produced by ureterosigmoidostomy, a procedure that was formerly used in the treatment of patients with carcinoma of the bladder. Reabsorption of chloride and hydrogen ions from urine in the colon is responsible for the acidosis.

Fanconi Syndrome

Renal Fanconi syndrome is characterized by generalized dysfunction of the proximal renal tubules with loss of amino acids, glucose, phosphate, uric acid, and bicarbonate in the absence of abnormal glomerular function. This results in systemic acidosis, hypophosphatemia, and dehydration, which lead to growth disturbance, rickets, and osteomalacia. Fanconi syndrome may be further classified into that caused by primary renal abnormalities, in which the underlying defect is located within the renal tubular cells, and that because of prerenal disorders, in which metabolic substances from outside the kidney lead to derangements in tubular function. Autosomal dominant Fanconi syndrome, associated with rickets and osteomalacia, is seen with mutations in *EHHADH*, a gene involved in peroxisomal oxidation of fatty acids,[108] and mutations in *HNF4A*, which also cause maturity-onset diabetes of the young 1.[109] Genetic and physical mapping studies have also identified a locus for autosomal dominant Fanconi syndrome at chromosome 15q15.3.[110]

Dent disease is an X-linked renal tubular disorder characterized by low–molecular weight proteinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, rickets, and renal failure and may include other features of the Fanconi syndrome. The disease results from mutations of the X-linked *CLCN5* gene that encodes a 74–amino acid protein chloride channel with 12 to 13 transmembrane domains.[111] Patients usually present with signs and symptoms of hypokalemia and osteomalacia. Healing of the skeletal disease has occurred with vitamin D, alkali, and potassium treatment.

Fanconi syndrome associated with systemic metabolic processes is seen in Lowe syndrome (also known as Dent-2), a rare X-linked disorder that involves the eyes, kidney, and nervous system and is manifested by congenital cataracts, cognitive impairment, and renal tubular dysfunction. The disorder results from mutations of the *OCRL* gene,[112] which leads to abnormalities in the actin cytoskeleton, impairing tight and adherens junction formation, resulting in tubular dysfunction.[113]

Nephropathic cystinosis is an autosomal recessive lysosomal storage disease characterized by chronic kidney disease and other complications, including the Fanconi syndrome. The disease is caused by mutation of the *CTNS* gene that encodes a transmembrane protein thought to transport cystine out of lysosomes.[114] Cystine accumulates in many tissues, including the kidneys, resulting in tubular dysfunction and subsequently glomerular failure.[115] Fanconi-Bickel syndrome, characterized by renal tubular phosphate wasting and hepatorenal glycogen accumulation, is a result of homozygous mutations in the SLC2A2 (GLUT2) glucose transporter.[116]

Inborn errors of metabolism can also cause Fanconi syndrome, most notably Wilson disease and hereditary tyrosinemia. Wilson disease is an autosomal recessive disease caused by mutations in the *ATP7B* gene that encodes a copper-transporting P-type ATPase that is required for incorporation of this metal into ceruloplasmin. Clinical and pathologic manifestations in Wilson disease are attributed to the toxic effects of copper accumulation in liver, kidney, brain, and cornea. Fanconi syndrome and associated rickets and osteomalacia may predominate or be the presenting feature.[117] Treatment of Wilson disease with D-penicillamine and zinc salts significantly attenuates the phenotype.[118] Hereditary tyrosinemia type I is an autosomal recessive disease caused by mutations in the fumarylacetoacetate hydrolase gene that encodes an enzyme involved in the last step of tyrosine degradation.[119] Tyrosine accumulates in the kidney, peripheral nerves, and liver, which can lead to the development of cirrhosis and hepatoma.

In addition to other rare inherited causes of Fanconi syndrome, the development of Fanconi syndrome in multiple myeloma has been attributed to the toxic effects of monoclonal light chains on the proximal renal tubule.[120] Although extremely rare, osteomalacia may develop in patients with multiple myeloma as a consequence of the renal phosphate wasting and hypophosphatemia. Osteomalacia associated with RTA has also been reported in patients with Sjögren syndrome[121] and in patients with heavy metal poisoning, particularly cadmium[122] and lead.[123] Pharmacologic agents including valproate, tenofovir,[124,125] adefovir,[126] ifosfamide,[127] and outdated tetracycline[128] have been reported to cause Fanconi syndrome as well. The skeletal disease in these settings is attributed to hypophosphatemia and systemic acidosis produced by impaired tubular function.

KEY POINTS

- The kidney is a critical regulator of mineral metabolism. Inadequate renal resorption of phosphate and systemic acidosis can lead to impaired skeletal mineralization in Fanconi syndrome.

Chronic Kidney Disease

Renal osteodystrophy comprises a heterogeneous group of skeletal disorders associated with chronic kidney disease. Before the introduction of hemodialysis, the major accompanying skeletal disorder was a high turnover state because of secondary or tertiary hyperparathyroidism. Following the introduction of hemodialysis and the widespread use of aluminum-containing gels as phosphate binders,[129] two patterns of osteomalacia emerged. In the first type, associated with high-turnover bone disease, increased osteoid accompanied by low circulating calcium and phosphorus levels was seen. The second type, "adynamic" bone disease, was associated with sparse osteoid, a reduction in bone formation rate and normal or slightly elevated calcium and phosphorus levels accompanied by skeletal pain and fractures. Chronic kidney disease mineral and bone disorder is discussed in greater detail in Chapter 61.

Aluminum, Fluoride, and Heavy Metal Intoxication

Aluminum is deposited on the mineralization surface of bone and impairs osteoblastic bone formation.[130] At high concentrations, it can inhibit the vitamin D 1-alpha-hydroxylase.[131]

In high concentrations, fluoride incorporates into the skeleton as calcium fluorhydroxyapatite crystals, increasing apparent bone density on radiographs and bone density exams. Ingestion of water and food high in fluoride, in combination with a low calcium diet, can result in severe skeletal deformities and rickets in children.[132]

Exposure to heavy metals like cadmium, lead, and mercury can also cause phosphaturia, impairing skeletal mineralization.[133]

Hypophosphatasia

Hypophosphatasia is a heritable disorder characterized by mutations in the tissue-nonspecific (bone/liver/kidney) isoenzyme of alkaline phosphatase (TNSALP).[134] Biochemical diagnosis is made with low serum nonspecific alkaline phosphatase levels. Autosomal recessive infantile hypophosphatasia presents with hypercalcemia, renal failure, and increased intracranial pressure. Skeletal features include enlarged cranial sutures, craniostenosis, dental abnormalities, enlarged epiphyses, and prominent costochondral junctions. Serum calcium and phosphorus levels are normal in the less severe forms of hypophosphatasia that present in older children. Genotype-phenotype correlations demonstrate that the extreme heterogeneity in phenotype among patients with hypophosphatasia is because of residual enzyme activity with some mutations.[135] Bone marrow transplants have been performed for life-threatening disease.[136] Currently, enzyme replacement therapy with asfotase alfa is used to treat infantile and juvenile-onset hypophosphatasia.[137] This therapy improves skeletal mineralization, mobility, muscle strength, and pain.[138]

Autosomal dominant hypophosphatasia presents during adult life and is characterized by variable penetrance. Although impaired bone mineralization may be seen, the disorder tends to be mild. The presence of low bone mineral density or fractures in middle-aged patients can often result in a misdiagnosis of osteoporosis. Inappropriate treatment with bisphosphonates can worsen the hypomineralization by impairing residual alkaline phosphatase activity.[139]

The decrease in TNSALP enzyme activity in blood and tissues results in an accumulation of PPi, impairing skeletal mineralization. TNSALP generates Pi locally by cleaving substrates including PPi into Pi to promote mineralization. Because PPi is a potent inhibitor of mineralization, accumulation of PPi in hypophosphatasia inhibits mineralization at sites of bone formation. TNSALP has broad substrate activity; thus, in patients with hypophosphatasia, phosphorylated molecules such as phosphorylethanolamine and phosphorylcholine are excreted in excessive amounts in the urine, and circulating levels of pyridoxal-5'-phosphate, another TNSALP substrate, are markedly elevated.[140,141] Hypophosphatasia is discussed in more detail in Chapter 59.

KEY POINTS

- Presentation of hypophosphatasia in adults can be mistaken for osteoporosis.

Osteopetrosis

Rickets also may occur in infantile osteopetrosis,[142] which is most commonly caused by mutation of the *TCIRG1* gene that encodes the a3 subunit of V0 complex of the V-ATPase proton pump, expressed primarily in osteoclasts and gastric epithelium. Although a low local calcium × phosphate product owing to impaired osteoclastic bone resorption has been implicated in the development of rickets, affected children may have impaired intestinal calcium absorption, leading to secondary hyperparathyroidism and hypophosphatemia, which leads to rickets. Mutations in SNX10, which account for a small percentage of affected individuals,[143] also impair both osteoclast activity and intestinal calcium absorption.[144] Osteopetrosis is discussed in greater detail in Chapter 59.

Fibrogenesis Imperfecta Ossium

Fibrogenesis imperfecta ossium is an extremely rare disorder characterized by progressively disabling skeletal pain, bone fragility, and skeletal deformities, seen primarily in middle-aged individuals. Serum calcium and phosphorus are normal, but alkaline phosphatase activity is increased. The radiographic abnormalities include thickened and amorphous-appearing trabeculae with spotty increases in density, reduced cortical thicknesses, and occasional pseudofractures. The abnormal “fishnet” trabecular pattern seen on conventional radiographs, combined with MRI of low–signal intensity bone marrow on T1- and T2-weighted images, is helpful in diagnosis.[145] The primary defect is thought to be abnormal collagen synthesis, leading to defective fibrillar organization and impaired mineralization of bone. The increased osteoid lacks the lamellar structure and typical birefringence that is characteristic of other osteomalacic states. Electron microscopy reveals that immature small-diameter collagen fibers are arranged in loops, as well as dense “whorls.” The abnormal bone matrix leads to increased bone fragility and fractures. Of interest, paraproteinemia is seen in approximately one-third of individuals.[146] No uniformly effective treatment has been found.

TREATMENT

Vitamin D deficiency impairs intestinal calcium absorption, resulting in secondary hyperparathyroidism, which leads to hypophosphatemia, rickets in the growing skeleton, and osteomalacia. Guidelines from the US Institute of Medicine suggest that, for over 97.5% of the population, the recommended vitamin D intake from age 1 to 70 years should be 600 IU, with an increase to 800 IU for those over 70 years of age.[39] Although this recommended intake is an increase from previous guidelines, there remains controversy as to whether or not these recommendations are sufficient.[40] Higher doses are required in those with obesity, intestinal disease, or short gut syndrome, as well as to treat rickets and osteomalacia. The goals for treatment of patients with osteomalacia or rickets are to correct hypocalcemia if it exists, to correct secondary hyperparathyroidism, and to correct hypophosphatemia. Careful monitoring may be required to prevent vitamin D intoxication, which leads to hypercalcemia, hypercalciuria, nephrocalcinosis, and nephrolithiasis. The dose of vitamin D must be tailored to a given individual, and calcium intake must be optimized to prevent secondary hyperparathyroidism and the resultant renal phosphate losses. Vitamin D is available in 400-IU (10-mcg) to 50,000-IU (1.25-mg) capsules for oral administration and liquid form (250–2000 IU or 6.25–50 mcg per drop) for oral administration. In patients with malabsorption, vitamin D can also be administered sublingually.[147] The advantages of vitamin D are its low cost and the endogenous regulation of activation to 1,25$(OH)_2$D. The disadvantages are that an optimal therapeutic response may take several weeks, and, in cases of toxicity, its biologic activity persists for several weeks after it is discontinued, because it has a long half-life.

1,25$(OH)_2$D3 (calcitriol) is available in 0.25-mcg and 0.50-mcg capsules, as well as in oral and intravenous preparations containing 1 to 2 mcg/mL. The advantages of calcitriol are its rapid onset of action and short half-life (>6 hours). However, hypercalcemia may occur even long after an apparently stable maintenance dose has been established. Because hypercalcemia during treatment with 1,25$(OH)_2$D3 is unpredictable, patients must be monitored closely. 1-alpha-(OH)D2 is approved for use in the treatment of secondary hyperparathyroidism in patients with chronic kidney disease.[148] It is marketed in 0.5- to 2.5-mcg capsules and solutions containing 2 mcg/mL. After administration, it undergoes conversion to 1,25(OH)2D2.

1-alpha hydroxylated metabolites are indicated for the treatment of diseases in which renal 1-alpha hydroxylation is diminished or impaired (hypoparathyroidism, pseudohypoparathyroidism, chronic kidney disease, pseudovitamin D–deficiency rickets, tumor-induced osteomalacia, and other FGF23-dependent hypophosphatemic disorders), or when there is resistance to 1,25$(OH)_2$D at the cellular level. Osteomalacia or rickets associated with hereditary vitamin D–resistant rickets, characterized by mutation of the VDR, occasionally responds to high-dose 1,25$(OH)_2$D3. However, long-term parenteral administration of calcium may be required to normalize PTH and phosphorus levels and heal skeletal disease[62] (also see Chapter 58).

In children with nutritional rickets caused by calcium deficiency, increasing the calcium intake to between 800 and 1500 mg per day was shown to heal the skeletal disease.[44,149] Several protocols are recommended for treatment of vitamin D–deficient skeletal disease. Daily oral doses of vitamin D, 50 mcg (2000 IU) for 3 to 12 weeks, when accompanied by an adequate calcium intake, may result in a biochemical response in classic rickets and osteomalacia resulting from simple vitamin D deficiency. However, this regimen is insufficient to treat rickets associated with FGF23 excess, malabsorption, and/or drugs that increase vitamin D metabolism. Alternative recommendations include treatment with larger doses of vitamin D (50,000–500,000 IU given in divided doses over 1–3 months), followed by maintenance doses of 600 IU per day, to achieve a normal circulating 25(OH)D level. Patients on chronic anticonvulsant therapy often require higher maintenance doses.[150] Administration of vitamin D to patients with vitamin D–deficiency rickets or osteomalacia invariably results in healing of the skeletal disease when calcium intake is adequate. Biochemical responses include normalization of serum calcium and phosphorus levels. There is often an initial increase in serum alkaline phosphatase, indicative of healing of the osteomalacic lesions, followed by a gradual fall in both alkaline phosphatase and PTH.

Hypercalcemia and hypercalciuria are potential complications of treatment with vitamin D. Hypercalcemia resulting from vitamin D intoxication is caused by a combination of increased intestinal absorption of calcium and increased osteoclastic bone resorption. Impaired kidney function may develop in the setting of hypercalcemia, hypercalciuria, nephrocalcinosis, and nephrolithiasis. Patients may exhibit classic hypercalcemic symptoms, including anorexia, nausea, vomiting, weight loss, headache, constipation, polyuria, polydipsia, and altered mental status. Aggressive hydration with intravenous fluids is indicated, but because elevated serum 25(OH)D levels persist, glucocorticoids may be required to lower serum calcium levels, as may intravenous bisphosphonates to inhibit osteoclastic bone resorption. Patients on long-term treatment with pharmacologic vitamin D metabolites should be carefully monitored with measurement of serum and urinary calcium and serum creatinine. This is critical because there is no way of predicting when or in whom vitamin D intoxication will develop and/or recur.

Treatment of hypophosphatemia not associated with vitamin D deficiency and secondary hyperparathyroidism involves oral supplementation with neutral phosphate salts, including sodium or potassium salts. The rise in serum phosphorus after a single oral dose of phosphate is transient; therefore, phosphate supplements must be administered at frequent intervals. The precise dose must be individualized and is dependent on the degree of renal loss. In individuals with severe renal losses, as much as 1000 mg of elemental phosphorus is required every 4 to 6 hours to promote sustained elevations of serum phosphorus values. Treatment response cannot be assessed with a single fasting determination of serum phosphorus; multiple measurements of serum values at various times after each dose are required. Emptying the capsules and dissolving the contents into water or other liquid may improve intestinal absorption. When therapy is initiated, most patients experience some degree of gastrointestinal distress, including cramps and diarrhea. Therefore, initial doses should be low, and increments should be gradually introduced as tolerated.

Oral phosphate can bind calcium, leading to impaired intestinal calcium absorption and a rise in PTH levels, which further increases renal phosphate losses. Chronic phosphate therapy can lead to secondary hyperparathyroidism and parathyroid autonomy; therefore, chronic oral phosphate therapy should be combined with $1,25(OH)_2D$ to prevent the rise in PTH and promote the intestinal absorption of calcium and phosphate. The use of a calcimimetic to decrease PTH secretion has been reported as adjuvant treatment for hereditary and acquired hypophosphatemia associated with impaired renal tubular reabsorption.[89,90] In the various types of prerenal Fanconi syndrome, the specific treatment of the underlying disorder often results in disappearance of or improvement in the renal tubular dysfunction, thus allowing healing of the associated skeletal disease. In several of these disorders, improvement in the skeletal disease can also be achieved by correcting the acidosis and hypophosphatemia (i.e., supplementation with alkali, oral phosphate, and vitamin D). Targeted therapies for other rare diseases are discussed in the relevant sections.

KEY POINTS

- Adequate vitamin D levels are needed to maintain calcium and phosphate absorption and prevent secondary hyperparathyroidism.
- Treatment of hypophosphatemia with phosphate supplementation should always be accompanied with concomitant administration of calcitriol to promote phosphate absorption and prevent secondary hypoparathyroidism.

CONCLUSION

Optimal skeletal mineralization and strength are dependent on normal circulating levels of calcium and phosphate, as well as normal pH. Although expansion of the growth plate in rickets is because of impaired phosphate-mediated hypertrophic chondrocyte apoptosis in the setting of hypophosphatemia, the regulation of mineral deposition into bone is more complex and less well understood. Many of the factors regulating mineralization have been elucidated by identifying the molecular basis for rare genetic disorders, complemented by detailed analyses in naturally occurring or genetically engineered murine homologs. These studies have also identified a novel role for osteocytes in the regulation of bone resorption and are expected to further elucidate the molecular mechanisms regulating mineralization.

Paget disease of bone (osteitis deformans) is a skeletal disorder of a focal nature that is an example of physiology gone awry. The primary disturbance appears to be an exaggeration of osteoclastic bone resorption that initially produces localized loss of bone. Usually, the disorder is not appreciated until secondary bone formation becomes so pronounced that it results in one or more enlarged and deformed bones. The clinical findings depend on which bones are affected and vary from discovery of an incidental radiologic or biochemical abnormality to devastating musculoskeletal disabilities with a variety of neurologic and systemic complications. Great progress has been made in our ability to treat this disorder, and knowledge of its pathogenesis is increasing.

INCIDENCE AND EPIDEMIOLOGY

Studies of the incidence of Paget disease are inherently imprecise, because many affected individuals are asymptomatic and have normal serum total alkaline phosphatase levels.[1] On the basis of autopsy studies[2,3] and review of radiographs, the prevalence of the disease has been 3% or greater in individuals older than 40 years of age in countries where the disease is common.[4]

A striking feature of the epidemiology of Paget disease is the great variability in prevalence estimates in different regions of the world, and even within a single country. A survey of hospital radiographs in patients older than 55 years of age in 31 British towns revealed a prevalence of Paget disease ranging from 2.3% in Aberdeen, Scotland to 8.3% in Lancaster, England.[5] A similar survey done throughout Europe found that only in France did the prevalence equal the lowest prevalence rates in Britain.[6] Australia, New Zealand, and the United States[7] have a relatively high prevalence, perhaps because of British migration. The disease appears to be rare in Asia. In Japan, the prevalence has been estimated to be 2.8 per million of the population.[8] In most studies, the prevalence of Paget disease in men slightly exceeds that in women.[2-7] A meta-analysis of the temporal changes in prevalence of Paget disease in a variety of countries indicates that there has been a considerable decrease in the populations studied, but that this is heterogeneous, even in the same country.[9]

Much emphasis has been placed on the increase in prevalence of Paget disease with aging. It has been estimated that the prevalence is nearly 10% by the ninth decade.[2-4] Conversely, the disease has rarely been reported in individuals younger than 20 years of age. Although Paget disease is most often recognized after 50 years of age, it is probably misleading to conclude that the disease is rare in younger individuals. As is discussed later, the obvious manifestations, such as skeletal deformity, probably evolve over decades. Failure to diagnose the earlier phases of the disease is no doubt because of lack of symptoms and minimal use of the radiologic and biochemical tests that would lead to an early diagnosis in younger individuals.

Since 1883, it has been appreciated that Paget disease may affect more than one member of a family.[10] In large studies, a family history of the disease has been obtained in 12.3% of 788 cases[11] (United States), 13.8% of 407 cases[12] (Great Britain), and 22.8% of 658 cases[13] (Australia). In the former two studies, a 7- to 10-fold increase in Paget disease was noted in relatives of patients in comparison with control groups. In a small study in Spain in which relatives of patients were screened with bone scans, 40% of patients had at least one first-degree relative with Paget disease.[14] Examination of the overall pattern of apparent transmission suggests an autosomal dominant mode of inheritance.[10]

The search for potential environmental factors in the pathogenesis of Paget disease has led to consideration of whether past ownership of dogs might be a risk factor,[15] but this has not been confirmed by subsequent studies. Occupational exposure to lead has been proposed as a possible factor in Paget disease.[16] In one study, levels of cortical bone lead were higher than those in control subjects, but trabecular bone lead was lower.[17] A more recent Canadian study reported that exposure to wood burning during childhood could be a pathogenic factor.[18] The possible role of viral infections will be reviewed later.

PATHOPHYSIOLOGY

KEY POINTS

- The primary underlying pathology of Paget disease is a localized increase in osteoclastic bone resorption.

Consideration of the radiologic and pathologic evolution of the lesions of Paget disease strongly suggests that the primary disturbance is localized acceleration of osteoclastic bone resorption. At the interface of normal bone and an advancing lesion, numerous osteoclasts are found in Howship's lacunae in cortical or trabecular bone.[2] Many of the osteoclasts are larger than normal (Fig. 63.1) and may have up to 100 nuclei in cross-section rather than the several found in normal osteoclasts.[19] Examination of the ultrastructure of osteoclasts in specimens of Paget disease reveals a striking and characteristic feature: the presence of microfilaments in the nucleus and, less frequently, in the cytoplasm.[20,21] These structures have not been observed in osteoclasts from normal subjects or in the bones of patients with primary or secondary hyperparathyroidism, osteoporosis, or osteomalacia. They also have not been observed in osteoblasts, osteocytes, or bone marrow cells in the lesions of Paget disease. The inclusions have been found in a small percentage of the multinucleated giant cells (osteoclasts) in giant-cell tumors of bone and in the osteoclasts of some patients with osteopetrosis and pyknodysostosis.[22] The structure of the microfilaments most closely resembles the nucleocapsids of viruses of the *Paramyxoviridae* family, a group of RNA viruses known to cause common childhood infections. Evidence of *Paramyxoviridae* nucleocapsid proteins[23,24] and messenger RNA[25,26] has been found in pagetic lesions. The full-length sequence of the measles virus nucleocapsid (*MVNP*) gene has been sequenced from a pagetic lesion of one patient.[27] The relevance of these findings to the cause of Paget disease is discussed later.

As osteoclastic resorption progresses in the cortex, individual osteons widen and become confluent with adjacent osteons. The resorptive area thereby may extend to the endosteal and periosteal surfaces. In trabecular bone of the medullary cavities, the osteolytic process results in a marked reduction in bone volume. Associated with both early cortical and trabecular lesions is a remarkable proliferation of fibrous tissue that replaces normal fatty or hematopoietic bone marrow. The fibrous stroma is highly vascular, and although arteriovenous shunts were previously thought to be present, this feature has not been confirmed with radiolabeled albumin microspheres.[28]

The earliest recognizable radiologic feature of Paget disease is a focal osteolytic lesion. The skull was first appreciated to be affected by circumscribed osteolytic lesions, and Schuller[29] applied the term *osteoporosis circumscripta* to this finding. One or more osteolytic foci may be present, most often in the frontal and occipital regions, and may be observed to coalesce slowly over a period of years (Fig. 63.2). Pure osteolytic lesions also may be detected in other regions of the skeleton, but less frequently. They are seldom observed in the vertebral column or pelvis. In the long bones, osteolytic lesions usually develop at either end of the bone, less often in the diaphysis.[29] Occasionally, osteolytic foci can be observed simultaneously at both ends of a bone. The junction of normal bone and the osteolytic lesion shows a characteristic radiologic appearance that is nearly diagnostic of Paget disease. The edge of the lesion usually assumes the shape of a flame or an inverted V (Fig. 63.3). Serial radiologic follow-up of untreated lesions has documented an average rate of extension of approximately 1 cm annually.[30] Bone biopsies taken during this earliest phase of Paget disease not unexpectedly reveal a marked increase in osteoclastic activity and thinning of the trabeculae.[31] Other striking features include fibrovascular marrow, numerous osteoblasts lining the trabeculae, and prominent woven bone. Thus, a discrepancy is found in the results of radiologic and pathologic examination of an osteolytic lesion. Although focal density is decreased on radiographs, histology demonstrates bone formation that is very active but is not sufficient to overcome the remarkable degree of osteoclastic bone resorption.

A more commonly observed stage of Paget disease is the mixed phase, in which osteoblastic (or osteosclerotic) features are intermixed with osteolytic features in an individual bone. This phase is best appreciated in long bones, in which one may observe the advancing osteolytic front adjacent to normal bone and, trailing this front,

a heterogeneous region of osteosclerosis superimposed on the region that had previously been dominated by the osteolytic process (see Fig. 63.3). Biopsies of the mixed phase reveal a characteristic abnormality of lamellar bone in both cortical and trabecular bone. The matrix is transformed into a bizarre "mosaic" pattern of irregularly juxtaposed pieces of lamellar bone separated by cement lines that have a scalloped outline. The irregularity probably reflects areas of previous osteoclastic resorption. The structure of the involved cortex is so disordered that complete osteons are rare, and the outer and inner circumferential lamellae and the interstitial lamella may be totally disrupted.

The same disordered matrix structure is seen in trabecular bone. Interspersed among the chaotic lamellae are patches of woven bone characterized by a random pattern of deposition of collagen fibers and a larger number of osteocytes per unit area of matrix. It has been suggested that the lacunae surrounding the osteocytes are larger than normal, and that this finding represents osteocytic osteolysis.[32] However, it is more likely that the increased size of the periosteocytic lacunae is simply a characteristic of woven bone and not a second type of bone resorption in Paget disease. At the surfaces of bone formation, plump osteoblasts are found in great number adjacent to abundant osteoid. This type of bone is seldom found in adults, except when associated with rapid remodeling of bone, such as occurs after a fracture or in response to tumor invasion of bone. Studies using quantitative histomorphometry of bone documented the marked degree of cellular activity underlying the dramatic changes in bone structure in Paget disease.[33] The total amount of osteoid and the percentage of the bone surface covered by osteoid may be increased 4-fold to 5-fold. The increase in osteoid is not associated with an increase in osteoid seam width, because the rate of calcification also is increased, as established by double labeling of bone-forming surfaces with tetracycline. No dynamic means of defining the rate of bone resorption is available, but the extent of the total bone surface exhibiting evidence of bone resorption averages approximately 6-fold that of normal individuals, and the number of osteoclasts may be increased as much as 10-fold. In the medullary cavities, the intense resorptive process may produce hemorrhagic cysts with encircling fibrous marrow containing macrophages filled with hemosiderin. These cysts are believed to result from rupture of multiple dilated vessels and ensuing microinfarctions.[34] In the mixed phase of Paget disease, not only does patchy sclerosis of bone become apparent on radiography, but a bone also may be enlarged. If the osteolytic process extends to the subperiosteal layer, bone formation may be stimulated to such an extent that the thickness and circumference of the bone are increased as a result of periosteal new bone formation. When the skull is affected, this process can produce as much as a 4-fold thickening of the calvarium, as was reported by Paget.[35] A patchy form of sclerosis is often of a "cotton-wool" character (Fig. 63.4). The skull may be so severely affected that platybasia, or basilar impression, may be a complication. Long bones may be shortened because of lateral bowing of the femur or anterior bowing of the tibia, or both. Later in the course of the disease, the tibia may exhibit severe lateral bowing. The pathogenesis of the slowly progressive deformity is not known but must be related to the state of abnormal remodeling of the bone. Frequently, fissure fractures are associated with the bowing deformity. These fractures are linear transverse radiolucencies that usually are present in the cortex of the convex aspect of the deformed bone. They often are multiple and may remain stable in appearance for years. They can be found in either osteopenic or osteosclerotic cortices and may be present even in the absence of deformity. Histologic examination of these lesions suggests that they are incomplete fractures.[2] Only a small percentage of these lesions progress to a complete transverse fracture, which has been seen more often in patients with a sclerotic cortex.

Even after osteosclerotic bone has invaded the previously osteolytic regions of affected bone, evidence of ongoing abnormal bone resorption can be seen in the form of secondary resorption fronts. These secondary fronts are commonly seen as clefts in the cortex of long bones and trail in the path of the primary front.

In the final stage of Paget disease, termed *osteoblastic* or *sclerotic*, the affected bone remains dense and retains the "mosaic" matrix pattern characteristic of Paget disease. Tubular bones show a loss of differentiation between cortical and trabecular bone, even with enlargement of the bone as a result of periosteal new bone formation, because the new bone is no longer compact bone. Much less cellular activity is present in sclerotic lesions. Osteoclasts are few or absent, but osteoblasts may still be seen to line bone surfaces. The marrow may remain fibrous, but the number of blood vessels is greatly reduced. Scattered chronic inflammatory cells may be present. Occasionally, parts of lesions are totally devoid of bone cells, and for this reason the concept of "burned-out" Paget disease has arisen. However, it is very unlikely that extensive

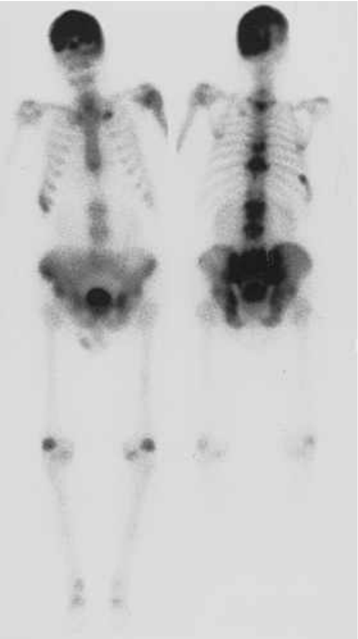

Fig. 63.5 **Anterior and Posterior Views of a Bone Scan in a Patient with Polyostotic Paget Disease.** Increased Uptake of Tracer Can be Noted in the Skull, Multiple Vertebrae, and the Pelvis, Areas in Which Paget Disease was Observed on Radiographs. The Other Abnormal Areas Probably Represent Degenerative Arthritis and a Healed Rib Fracture.

lesions of Paget disease ever achieve an entirely burned-out state. On the contrary, the presence of all stages of the disease in a single bone is much more likely.

The evolution of Paget disease can also be observed by administration of radioactive tracers and scanning of the entire skeleton or selected regions. Bone scans use technetium-labeled bisphosphonates, which, after intravenous injection, localize to skeletal sites in proportion to the relative blood flow and the rate of bone formation. The scans usually, but not always, demonstrate high uptake of radioactivity in the areas of the skeleton noted to be radiographically abnormal[36] (Fig. 63.5). In a small proportion of patients, increased uptake may be seen when the radiograph is normal, thus illustrating the great sensitivity of bone scans. On the contrary, a small percentage of sclerotic lesions may not be picked up by a bone scan. These lesions appear to represent areas of inactive disease. Bone scans can be analyzed semiquantitatively or by computer and thus may be used to monitor response to treatment.

Gallium scans, most often used to detect occult infection or tumors, also have been shown to delineate the lesions of Paget disease.[37] Evidence indicates that tracer gallium is localized to the nuclei of osteoclasts.[38] Therefore, the gallium scan may serve as a direct index of cellular activity in Paget disease.

CLINICAL FEATURES

KEY POINTS

- A significant proportion of patients have neither symptoms nor signs of the disease.

A considerable proportion of individuals with Paget disease have neither symptoms nor signs of the disease.[1] The disease is accidentally discovered in these cases because of radiologic or biochemical abnormalities uncovered during investigation of another disorder.

The most common clinical problems are pain and deformity. The bone pain of Paget disease, when present, is seldom severe. Usually it is a dull pain, is located deep below the soft tissues, and often persists during the night. In weight-bearing bone, the pain may be slightly worsened by ambulation, but to a lesser extent than pain originating from the joints or from nerve impingement. Deformity of the skeleton is most often noted in the skull and the lower extremity. Over many years, the hat size of an affected individual may be noted to increase. Bowing and enlargement of the femur and tibia also may evolve over a period of years.

Regional Manifestations

The Skull. In the absence of an enlarged cranium, symptoms in the skull are uncommon. Even with an enlarged cranium, symptoms often are absent. Certainly, the most common symptom (30%–50%) is hearing loss,[39] which is slowly progressive in untreated patients. Vertigo or tinnitus or both are much less common. The main mechanism of hearing loss in Paget disease has been attributed to a reduction in bone mineral density of the cochlear capsule.[40]

Much more serious complications of Paget disease may occur in the advanced stage of the disease in a small number of patients. The weight of the skull may be so great that the ability of the patient to keep the head erect is impaired. Muscle spasm may then produce pain in the neck and tension headaches. Neurologic abnormalities may be found in such patients as a consequence of basilar invagination or platybasia. Although they are unusual complications, even in the presence of radiologic evidence of basilar invagination compression of structures in the posterior fossa or cerebellar tonsillar herniation may produce ataxia, muscle weakness, and impaired respiration. Hydrocephalus also has been noted to be a rare complication and may be manifested by impaired gait, urinary incontinence, and some degree of dementia.

Finally, severe skull disease may be associated with the vague findings of a withdrawn individual who is somnolent and weak. It has been suggested that this manifestation might be a consequence of shunting of blood from the brain vessels to the external carotid artery system, a possible pagetic steal syndrome.[41] These symptoms also could represent a psychological response to disability, inasmuch as nearly 50% of patients in one study have been reported to have depression.[42]

The Jaws. Paget disease may affect the facial bones and jaw, but such involvement is uncommon. *Leontiasis ossea* is the descriptive term applied to a patient with enlargement of all the facial bones, but such deformity is more likely to be found in fibrous dysplasia.

Involvement of the mandible or maxilla may produce progressive root resorption leading to the loss of teeth.[43] In the more advanced stages of Paget disease, excessive formation of the cementum is associated with absence of the lamina dura and periodontal membranes. Facial disfigurement may occur from enlargement of the maxilla or mandible or both and is associated with spreading of the teeth and malocclusion. Edentulous patients have difficulty acquiring properly fitting dentures. Oral surgery may be complicated by excessive intraoperative bleeding and postoperative osteomyelitis. Tooth extractions may prove difficult because of ankylosis resulting from hyperplasia of the cementum.

The Spine. Neck pain and back pain are common complaints in an aging population of patients with Paget disease. Visualization of Paget disease in one or more vertebrae on radiographic examination often leads clinicians to conclude that they are dealing with bone pain, and treatment is instituted. However, most patients with moderate to severe pain have a complication associated with Paget disease as the cause of the pain rather than bone pain alone.

Paget disease affects the lumbar and sacral regions most frequently. One vertebra or many vertebrae may be involved. In the early osteolytic phase, which often is not recognized, the vertebral body appears osteoporotic and, in rare cases, may undergo so much resorption that it takes the shape of a thin transverse rod. Much more often, the vertebral bodies become enlarged overall, with thickened margins and coarse vertical striations centrally. Compression of a sclerotic vertebral body may develop because of the abnormal mechanical properties produced by the chaotic microarchitecture.

Severe pain or impaired neurologic function or both may result from compression of the spinal cord or nerve roots.[44] This complication can arise from enlargement of the vertebral bodies, pedicles, or laminae, as well as from compression fractures. It also has been suggested that shunting of blood may occur from the spinal arteries to the highly vascular bone.[45] Neurologic syndromes are more likely to develop with thoracic involvement. Symptoms include back pain, difficult ambulation, numbness, paresthesias of the feet, and progressive paresis of the legs. Later problems can include impaired bladder and bowel function, as well as spastic paraparesis and loss of sensation. Computed tomography (CT) and magnetic resonance imaging (MRI) are particularly helpful in resolving the anatomic abnormalities producing the disturbed function.

A rare complication in the spine is the development of a discrete paraspinal mass consisting of a central marrow cavity surrounded by pagetic bone that extends from the vertebrae.[46] It may appear that the lesion represents a neoplasm, but careful analysis of prior radiologic studies may reveal the chronic nature of the lesion and may make it unnecessary to perform a biopsy.

The other major causes of back pain in Paget disease are intervertebral disc disease and degenerative arthritis. No evidence indicates that disc degeneration is more common in patients with Paget disease, but it has been reported that the pagetic process can invade the disc and produce bony bridging across the disc space.[47] Back pain in the lumbar region is frequently associated with degenerative arthritis,[48] particularly when distortion of the facet joints is associated with Paget disease. Large osteophytes also may be found in association with enlarged vertebral bodies or where a compression fracture has occurred. A syndrome mimicking ankylosing spondylitis may occur in the presence of extensive osteophyte formation or with ossification of spinal ligaments,[49] but the human leukocyte antigen–B27 antigen is absent. However, classic ankylosing spondylitis has been found in association with Paget disease.[48]

The Pelvis and Extremities. The main symptoms associated with pelvic and lower extremity involvement are pain and impaired ambulation. Pain is seldom a significant symptom in the osteolytic phase of the disease. Hip pain is most common when both the acetabulum and the proximal end of the femur are affected by the sclerotic phase of the disease.[49] Bowing of the femur and protrusio acetabuli are often associated with pain aggravated by weight bearing. Many patients are relatively comfortable when not weight bearing, unlike patients with bone pain, who usually have nocturnal discomfort.

Knee pain and occasionally joint effusions may occur with sclerotic disease affecting the femur or tibia or both. Distortion of the knee joint produced by enlargement of the distal end of the femur or the proximal part of the tibia and severe bowing of either bone can induce mechanical strains on the articular cartilage and thereby accelerate the degenerative process. The pagetic process in subchondral bone also may contribute to joint disease. A similar set of circumstances may account for ankle pain.

Fractures of the lower extremity are more likely to affect the femur than the tibia. In the largest series of reported femoral fractures, the subtrochanteric region was the most common site of fracture (49 of 182), and the rate of nonunion was noted to be 40%, a figure considerably greater than was previously appreciated.[50] Nonunion appears to be less common after tibial fractures.

Involvement of the upper-extremity long bones is much less likely to produce symptoms, although deformity may be apparent. At the shoulder, impaired rotator cuff function may be noted when overgrowth of bone leads to anatomic distortion of the glenohumeral joint.

Occasionally, patients who have Paget disease affecting the foot have pain on weight bearing. Symptoms are seldom encountered in individuals with radiologic evidence of Paget disease in the hands.

Sarcoma, Giant-Cell Tumors, and Nonskeletal Malignancies

The most feared complication in Paget disease is sarcoma. It has been estimated that 10% of patients with extensive disease may experience this problem, but if all affected individuals are considered, the incidence is probably less than 1%.[52] Sarcomas have rarely been reported to develop in multiple members of families with Paget disease. This will be discussed in the Genetics section.

Patients in whom sarcomas develop usually have pain and swelling, always in an area previously affected by Paget disease. Occasionally, fracture at the tumor site may lead to discovery of the neoplasm. Tumors most often arise in the pelvis, femur, humerus, skull, and facial bones.[52] Multifocal sarcomas are found only in patients with advanced and widespread polyostotic disease and are thought to represent tumors of independent origin rather than metastases.[53]

The histology of sarcomas is quite variable. Fibrosarcomas, chondrosarcomas, osteogenic sarcomas, and anaplastic sarcomas may be found. Variable numbers of multinucleated giant cells (probably osteoclasts) may be scattered throughout the tumor stroma and most likely are not neoplastic. The nuclear inclusions typical of Paget disease have been observed in giant cells but not in the tumor cells.[54] It is not unusual for several histologic patterns to be present in a single tumor, which suggests that a common stem cell may give rise to a variety of better differentiated mesenchymal cells.

Lymphomas and multiple myelomas have been found in association with Paget disease[51] but probably represent chance occurrences rather than a complication of the pathologic process.

It is difficult to detect early sarcoma formation by radiologic examination, because of the underlying distortion of pagetic bone. Because they appear to arise in medullary bone, an early finding may be a subcortical osteolytic lesion. Only when a radiolucent focus with speckled areas of calcification has broken through the confines of the cortex is it apparent that a malignant neoplasm is present. CT or MRI is the best means of determining the extent of the tumor mass.

The rate of change in serum alkaline phosphatase activity has not proved to be a useful marker for the development of sarcomas, despite early reports that this might be the case.

The life expectancy for the average patient in whom a sarcoma develops is sadly brief, perhaps because of the difficulty associated with early detection. In one study, only 7.5% of patients survived 5 years, whereas a 37% 5-year survival rate was noted in older adult patients who were free of underlying Paget disease.[55]

Giant-cell tumors of bone, which usually follow a benign course and most often are found at the ends of long bones in otherwise normal individuals, may arise in the lesions of Paget disease.[56] They appear to be much less common than sarcoma in Paget disease and have frequently been noted to originate in the skull and facial bones. Rarely, these tumors have been reported in multiple family members who have Paget disease.[57]

These tumors are characterized by spindle-shaped cells with fusiform nuclei and clumped chromatin or nuclei and by scattered multinucleated giant cells. Mitoses are rarely found in either the mononuclear or giant cells. The giant cells contain the nuclear inclusions of Paget disease, but the stromal cells do not.[56] The opinion has been expressed that many of the reported cases of giant-cell tumor in Paget disease actually represent giant-cell reparative granulomas, which are common lesions arising in the jaw.[58]

Surgery and radiation have been used to treat symptomatic giant-cell tumors in Paget disease. In one patient, high doses of dexamethasone were effective in shrinking an extraskeletal tumor.[59] Another patient responded to the antiresorptive agent, denosumab.[60]

BIOCHEMICAL FEATURES

The intense cellular activity in active lesions of Paget disease may be reflected in various biochemical markers of bone resorption and bone formation. In most patients who come to clinical attention, biochemical markers do reflect the extent and activity of the disease, although patients with only a small percentage of affected skeleton have no biochemical abnormalities.

Indices of Bone Resorption

The increased bone resorption typical of active Paget disease might be expected to produce an increase in serum and urinary calcium levels, but in the absence of fractures or immobilization, hypercalcemia or hypercalciuria is not a prominent feature of Paget disease.[61] It is generally believed that this finding is explained by a concomitant increase in bone formation that is demonstrable histologically and by kinetic analysis of plasma disappearance rates and skeletal uptake of radiocalcium[61] or other skeletal tracers. A variety of bone collagen matrix breakdown products have been used as indices of bone resorption. These products include urinary hydroxyproline, total and free pyridinoline and deoxypyridinoline, type 1 collagen N-telopeptide, and type 1 collagen C-telopeptide. The telopeptide assays appear to be most specific for bone collagen resorption. Measurement of non-isomerized fragments of collagen type 1 C-telopeptide may be the most sensitive means of evaluating bone resorption in patients with Paget disease.[62]

Indices of Bone Formation

Since 1929, it has been appreciated that serum total alkaline phosphatase activity may be increased in patients with Paget disease.[63] The enzyme is localized at the plasma membrane in osteoblasts and may participate in the mineralization of bone matrix. In Paget disease, enzyme activity in the circulation correlates with the extent of disease on radiographic skeletal surveys, as well as with total urinary hydroxyproline.[49] Effective treatment of Paget disease reduces total alkaline phosphatase activity by 50% or more.

During long-term follow-up of untreated patients with Paget disease, alkaline phosphatase activity usually exhibits a gradual increase or no significant change.[64] In some patients, major fluctuations may represent technical errors rather than changes in disease activity. In the presence of liver disease, hepatic alkaline phosphatase activity may interfere with an accurate assessment of Paget disease activity. In such patients, measurement of procollagen type 1 N-terminal peptide levels by immunoassay is preferable.[65]

Serum osteocalcin or bone Gla protein is a nearly specific product of osteoblasts that may be elevated in Paget disease, but not to the same degree as serum alkaline phosphatase activity.[66] Paradoxically, treatment of patients with drugs that reduce turnover may produce a transient increase in osteocalcin levels.[65] A potential explanation for these observations is that osteocalcin gene expression is reduced in active Paget disease.[67]

Serum levels of procollagen type 1 N-terminal peptide correlate significantly with quantitative bone scintigraphy and decline with treatment of Paget disease to a greater extent than bone-specific alkaline phosphatase.[65]

Because of the cost-effectiveness of the serum total alkaline phosphatase assay, this remains a reasonable choice for the biochemical assessment of the average patient with Paget disease.

Calciotropic Hormones

Calcitonin secretion is normal in patients with Paget disease.[68] Parathyroid hormone concentrations generally are within the normal range, but elevated concentrations have been found in subsets of patients.[69,70] This observation could be related to renal failure, vitamin D deficiency, or subtle hypocalcemia related to a higher rate of bone formation than bone resorption. Primary hyperparathyroidism may be a coincidental disorder.

Patients with adequate vitamin D intake or sufficient ultraviolet light exposure or both have normal 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D levels. In two studies, serum 24,25-dihydroxyvitamin D was reported to be low and to correlate inversely with disease activity.[71,72] The pathogenesis and clinical relevance of this finding remain unknown.

Interleukin-6, an important local modulator of osteoclast function, has been reported to be elevated in the bone marrow of patients with Paget disease[73] and in serum by some,[73-75] but not all, investigators.[76] Receptor activator of nuclear factor-κ beta ligand (RANKL) and osteoprotegerin (OPG), a decoy receptor for RANKL, are key modulators of osteoclast function. Serum measurements in patients with Paget disease have also been variable, but one study indicates that both RANKL and OPG levels may be highly elevated, and that bisphosphonate therapy can increase OPG, and to a lesser extent reduce RANKL levels, thereby reducing the RANKL/OPG ratio.[77]

SYSTEMIC COMPLICATIONS AND ASSOCIATED DISEASES

Primary Hyperparathyroidism, Nephrolithiasis, Hypercalciuria, Hypercalcemia

In a recent large study in Italy, it was reported that the prevalence of nephrolithiasis and primary hyperparathyroidism was greater than in a control group.[78] Hyperoxaluria was a prominent feature in the nephrolithiasis patients. The explanation for these findings remains to be established.

Hypercalciuria is readily provoked by immobilization after fracture[79] or neurologic injury. In this setting bone resorption increases, whereas bone formation decreases.

In addition to primary hyperparathyroidism,[78,80] hypercalcemia also may occur as a consequence of immobilization[79] or malignancy.[81]

Hyperuricemia and Gout

Serum uric acid concentrations have been reported to be elevated primarily in men with relatively severe Paget disease.[49] Nearly half of the hyperuricemic men had clinical episodes of gouty arthritis. Paget disease also was found to be present in 23% of a group of patients with gout.[82] It is possible that a high turnover of nucleic acids in the lesions of Paget disease could increase the urate pool sufficiently to account for these observations.[83]

Cardiovascular Abnormalities

Increased cardiac output has been found to be present in patients who have at least 15% of their skeleton affected by Paget disease.[84] This

TABLE 63.1 Indications for Drug Treatment in Paget Disease

Bone pain

Hypercalcemia
Neurologic deficit from vertebral disease
Prevention of hearing loss
Prevention of complications in young patients

abnormality is often associated with left ventricular hypertrophy. The excessive vascularity of the soft tissue and adjacent pagetic bone must be factors contributing to these phenomena. In addition, a reduction in peripheral vascular resistance may lead to increased cardiac output.[85] High-output cardiac failure may occur but seems to be unusual.

Calcific aortic stenosis appears to be four to six times more common in patients with Paget disease than in a control population.[86,87] It is more likely to be found in patients with severe disease, which suggests that increased cardiac output producing turbulence across the valve may induce calcification. Intracardiac calcification also may occur in the interventricular septum and may produce a complete heart block.[87,88] Arterial calcification of peripheral vessels in patients with Paget disease is also greater than in control subjects.[89]

DRUG TREATMENT

Indications for Treatment

Indications for drug treatment of Paget disease are listed in Table 63.1. Perhaps the most common reason for treatment is bone pain. When Paget disease occurs adjacent to a joint, it may be difficult to distinguish bone pain from joint pain. In such cases, drug therapy may be particularly useful in clarifying the origin of the pain. Pretreatment of patients who require elective orthopedic surgery may prevent complications such as intraoperative or postoperative hemorrhage and immobilization hypercalcemia. Hypercalciuria and hypercalcemia can be reversed or prevented by drug treatment, but these indications are uncommon.

KEY POINTS

- If bone pain is present, or if there is skeletal involvement likely to produce significant complications, a single 5-mg infusion of zoledronic acid can sup-press disease activity for up to 6.5 years.

Some patients with neurologic deficits associated with vertebral disease may experience dramatic remission of their signs and symptoms. Although hearing loss is seldom reversed, preservation of auditory acuity is expected. Reduction of disease activity produces a decrease in cardiac output. It is possible that early treatment could prevent future complications such as skeletal deformity, but no long-term randomized clinical trials have been completed.

Certainly, many patients do not need to be treated. The decision to treat must take into consideration the present symptoms, the likelihood of future complications, the cost of therapy, and the mode of administration.

Pretreatment Laboratory Evaluation

Measurement of serum total alkaline phosphatase activity in a reliable laboratory is probably the only biochemical test needed for most patients. Radiographs of known lesions of Paget disease should be performed to ensure awareness of osteolytic lesions. In patients whose extent of disease is unknown, a bone scan is the best means of defining the regions of the skeleton requiring radiographic evaluation.

Calcitonin

Calcitonin is a peptide hormone that binds to receptors on osteoclasts and can rapidly inhibit bone resorption. Salmon calcitonin was approved for clinical use in the United States in 1975 and was the first therapy useful in treating Paget disease. Subcutaneous injections three to seven times weekly were effective in reducing bone pain, cardiac output, and vascularity of affected bones, reversing some neurologic deficits, and stabilizing hearing deficits.[90] Bone resorption and formation parameters were reduced by 50% in 3 to 6 months. Unfortunately, high antibody titers induced by the hormone caused loss of responsiveness in approximately 26% of patients.[90] Human calcitonin was effective in these patients until its manufacture was terminated. At this time salmon calcitonin is seldom used because of the availability of more effective therapy.

Bisphosphonates

Bisphosphonates are analogs of inorganic pyrophosphate, a compound thought to participate in the mineralization of bone. By substituting a P-C-P bond for the naturally occurring P-O-P bond, a family of metabolically stable compounds has been produced that bind to hydroxyapatite and inhibit bone resorption and, secondarily, bone formation in experimental animals and humans. The earliest bisphosphonates, such as etidronate, induce osteoclast apoptosis by producing nonhydrolyzable analogs of adenosine triphosphate, whereas the more potent aminobisphosphonates inhibit farnesyl-diphosphate synthase in the mevalonate pathway, which produces osteoclast apoptosis by inhibition of protein prenylation.[91]

Four oral bisphosphonates taken daily are etidronate[92] (5 mg/kg body weight for 6 months), alendronate[93] (40 mg for 6 months), tiludronate[94] (400 mg for 3 months), and risedronate[95] (30 mg for 2 months). Pamidronate is available in intravenous form and is commonly infused once over a period of several hours at a dose of 60 mg for patients with less than 5-fold elevations of serum total alkaline phosphatase activity[96] and at an intermittent dose of 60 or 90 mg on 2 or more days, depending on the level of alkaline phosphatase and the response to each infusion. Zoledronic acid, the most recently approved agent, is administered as a 5-mg dose intravenously over 15 minutes.[97]

The bisphosphonates taken orally must be ingested with water only on an empty stomach, because they are poorly absorbed. Generally, side effects are not a major problem and, when present, include abdominal distress, diarrhea, and a temporary increase in bone pain. Patients who receive pamidronate or zoledronic acid intravenously may experience fever and myalgias for approximately 24 hours or more. This acute-phase response is a consequence of cytokine release from gamma delta T cells and appears to be accentuated in patients with serum 25OHD levels below 30 ng/mL.[98] This side effect seldom occurs with subsequent infusions. Allergic reactions are rare and most often are inflammatory eye reactions associated with pamidronate use. Etidronate is the only bisphosphonate reported to produce significant osteomalacia, usually at a dose greater than 5 mg/kg body weight daily. This drug is now rarely used, given the existence of better agents. Renal toxicity is not observed with intravenous zoledronic acid if the drug is infused as approved, and the creatinine clearance is 35 cc/min or higher.[99] Osteonecrosis of the jaw, an unusual event in cancer patients treated monthly with intravenous bisphosphonates, is extremely uncommon in patients with Paget disease or osteoporosis.[100]

The potent aminobisphosphonates can induce biochemical remissions in the great majority of patients with mild to moderate disease activity. Only zoledronic acid can consistently normalize biochemical parameters in the most severely affected patients,[97] and the response

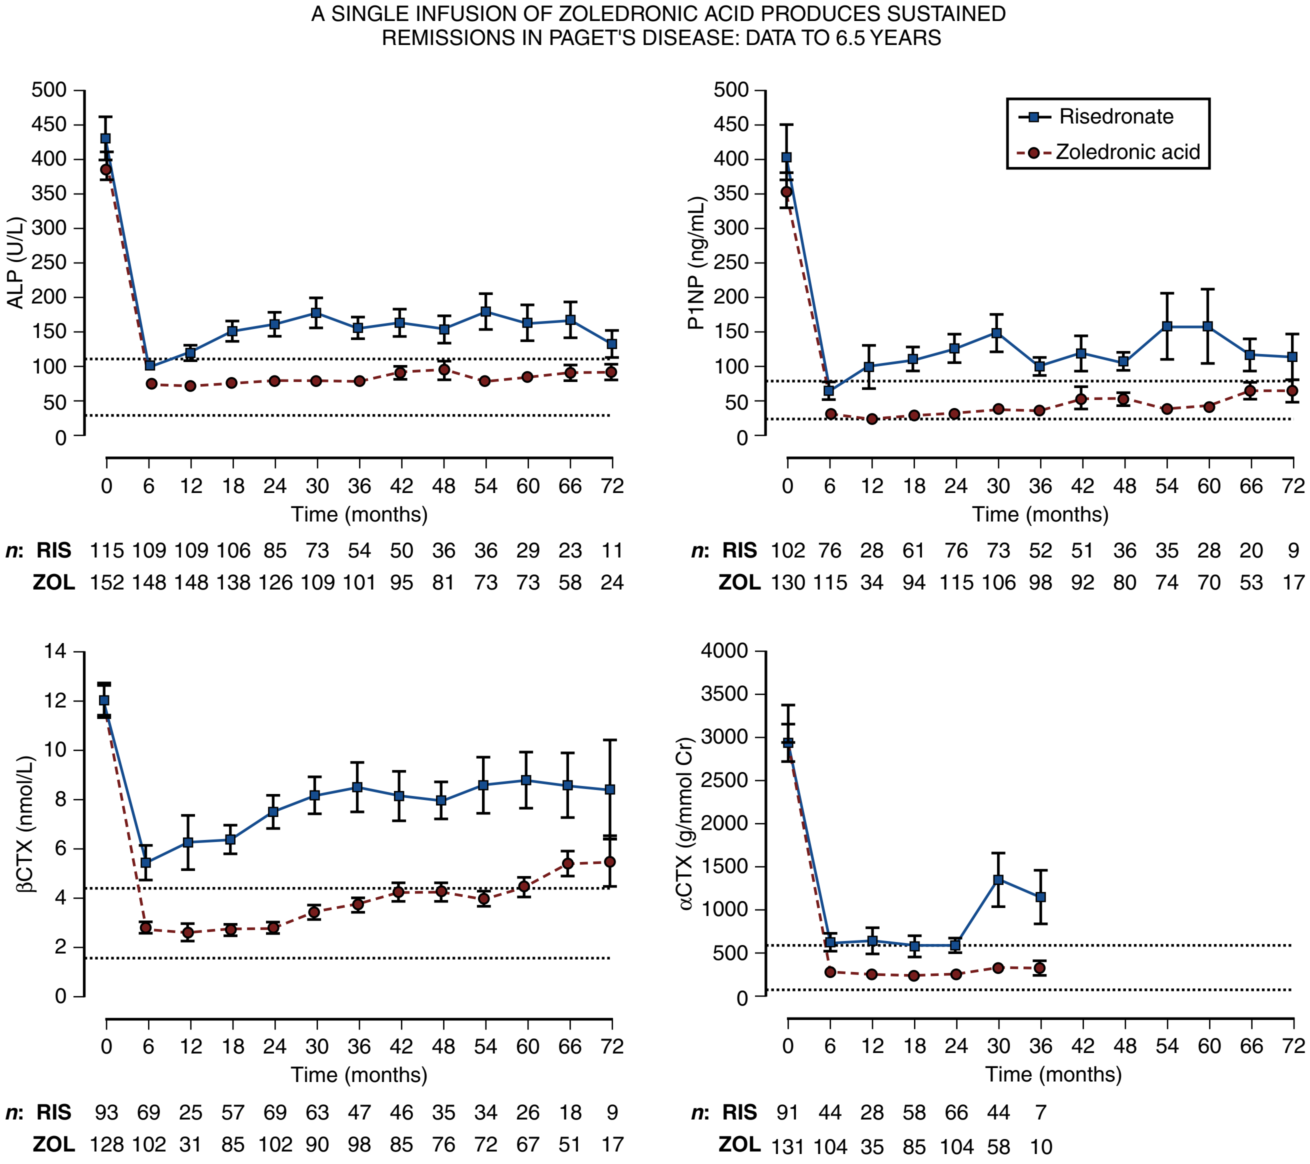

Fig. 63.6 **Comparison of the Long-Term Suppression of Bone Turnover Markers by a 5-mg Single Infusion of Zoledronic Acid (*ZOL*) or a 2-Month Course of Risedronate (*RIS*) tablets, 30 mg/day.** Bone Formation Markers, Alkaline Phosphatase (*ALP*) and N-Terminal Propeptide of Type 1 Collagen (*P1NP*), and Bone Resorption Markers, Serum Beta-C-Telopeptide (*beta CTX*) and Urine Alpha–C-Telopeptide (*alpha-CTX*) Remained Suppressed Up to 6.5 Years After Zoledronic Acid Infusion. Risedronate Had a Lesser Effect, and Patients Dropped Out of the Study After Relapse. The *Dotted Lines* Indicate the Reference Ranges. The Data are Presented as Mean ± Standard Error of the Mean. (From Reid IR, Lyles K, Su G, et al. A single infusion of zoledronic acid produces sustained remissions in Paget disease: data to 6.5 years. *J Bone Miner Res.* 2011;26:2261–2270.)

can persist for up to 6.5 years[101] (Fig. 63.6). It remains to be seen whether long-term biochemical suppression, an achievable goal in most patients, can reduce the incidence of complications in patients who are most at risk. These individuals include those with skull, vertebral, pelvic, and lower-extremity involvement.

If there is a contraindication to use of a bisphosphonate such as renal failure, denosumab may be effective and safe, as reported in one such patient.[102]

TREATMENT AND POSTTREATMENT LABORATORY EVALUATION

For most patients, measurement of total serum alkaline phosphatase activity is sufficient to determine the success of treatment. In patients with known osteolytic lesions on radiologic examination, an annual evaluation should be adequate.

Surgery

Certainly, the benefits of surgery for the appropriate indications in patients with Paget disease outweigh the potential complications of excessive hemorrhage and impaired healing. Hemorrhage is less likely if patients are treated with an effective drug preoperatively. Probably the most common reason for orthopedic surgery is total hip replacement.[103] The rate of success in relieving intractable hip pain and improving mobility is excellent. Heterotopic ossification may be somewhat more common postoperatively but is seldom a major problem. Total knee replacement is also a successful procedure.[104] Tibial and fibular osteotomies to correct varus deformity of the tibia are impressive in relieving knee and ankle pain associated with marked deformity.[105] Because the rate of nonunion is relatively high in femoral fractures, open reduction and fixation of these fractures may prove necessary.

Much less commonly required are suboccipital craniectomy and upper cervical vertebral laminectomy in patients with symptomatic basilar impression. Equally uncommon is the need for ventricular shunting in patients with hydrocephalus. Attempted relief of hearing loss in patients with skull loss by stapes mobilization or stapedectomy has been of questionable benefit. Surgery to correct spinal stenosis or nerve root compression has generally been successful.

Causes

Genetics. In 2002, a mutation in the sequestosome 1 (*SQSTM1*) gene on chromosome 5 was reported in 11 of 24 French Canadian families with Paget disease and in 18 of 112 patients with apparently sporadic disease (see Chapter 59).[106] By 2010, at least 20 separate mutations of this gene were documented in a variety of countries.[107] The mutations are mainly clustered around the ubiquitin-binding domain of the SQSTM1 protein. The SQSTM1 protein modulates activity of the nuclear factor kappa B pathway, an important mediator of osteoclast function, and is involved in the process of autophagy. It is unlikely that mutations of this gene entirely account for a pagetic phenotype, because many of the family members of these pedigrees exhibit no evidence of Paget disease yet harbor one of the mutations.[108-111] For example, in New Zealand only four in 23 children with the same mutation inherited from a parent with Paget disease had bone scan evidence of the disorder at an average age of 44 years.[110] Similarly, in the Netherlands only 7.1% of individuals with *SQSTM1* mutations developed Paget disease when followed over a 15-year period.[111] In the past 10 years, 14 new susceptibility loci for Paget disease have been discovered.[112] These are likely to influence bone metabolism (*CSF1,* TNFRSF11A, *PML, TM7SF4, UCMA/GRP, DKK1, CTHRC1, OPTN, RIN3, hnRNPA2B7, FKBP5, ZNF687, BER,* and *C9ORF72* hexanucleotide repeat expansion frequency). Also, it has been indicated that patients who harbor *SQTM1* mutations plus mutation at one of these loci may have a more severe phenotype.[113] In Italy two groups have reported loss-of-function mutations in the profilin 1 gene that were associated with the early onset of a polyostotic Paget-like disease in family members.[114,115] In one kindred, sarcomas were a complication in three out of 11 family members.[114] In the other family, one out of eight patients developed a sarcoma, and there was considerable difficulty in successfully treating the patients with standard drug therapy, including multiple doses of zoledronate[115]

A rare syndrome of Paget disease, inclusion body myositis and frontotemporal dementia, also has a genetic association. Mutations in valosine-containing protein (VCP) are found in this syndrome.[116] This protein also contains a ubiquitin-binding domain and has effects on autophagy. As in the case of patients with classical familial Paget disease who have *SQTM1* mutations, there is incomplete penetrance of the skeletal disorder in individuals who have a VCP mutation; approximately 50% are affected.[116] Several rare heritable osteolytic disorders superficially resemble Paget disease.[117] These are caused by mutations that affect RANK or OPG (see Chapter 59).

Slow Virus Infection. The presence of osteoclast nuclear and cytoplasmic microfilaments essentially identical in structure to nucleocapsids of the *Paramyxoviridae* virus family initially suggested the possibility that Paget disease was caused by a slow virus infection.[20,21] Subsequent immunochemical studies[23,24] and sequence analysis of *MVNP* transcripts[25-27] have added support to the hypothesis, although not all studies have positively demonstrated a viral presence.[118,119] Further evidence for a role of measles virus in the pathogenesis of the disorder is indicated by *in vitro* studies carried out on pelvic bone marrow aspirations from patients with Paget disease. Osteoclasts generated in culture from osteoclast precursors exhibit a "pagetic phenotype" that distinguishes them from normal osteoclasts.[120] There are increased numbers generated, increased nuclei/osteoclast, increased bone resorption capacity/osteoclast, increased 1,25$(OH)_2D_3$ sensitivity, increased TAF-12 expression, and increased RANKL and tumor necrosis factor (TNF) sensitivity. They also secrete high levels of IL-6. When normal osteoclasts were transduced with MVNP, they were transformed into cells with the "pagetic phenotype."[121] Finally, when antisense-*MVNP* was tested on osteoclasts generated from the marrow of patients expressing MVNP, the "pagetic phenotype" was abolished.[122]

Animal Models of Paget Disease

Transgenic mice have been used to further address the pathogenesis of Paget disease.[122-127] In two studies, the most common *SQSMT1* mutation found in familial Paget disease (*SQSTM1/p62P394L*) was inserted into transgenic mice. In the first study, increased osteoclastic activity without increased bone formation was reported in lumbar vertebrae,[124] while in the second study generalized osteoclastic activity was found in the femur and tibia, with small areas of osteoblastic activity at the ends of these long bones.[127] In both studies, osteoclast precursors were hyperresponsive to RANKL, but in the first study the precursors were not hyperresponsive to 1,25$(OH)_2D_3$, a feature of pagetic osteoclasts. This was not tested in the second study. Transgenic mice were also generated with VCP mutations in two studies.[125,126] In both studies, the dominant lesions in the long bones were severe osteopenia with occasional hypersensitivity to TNF or RANKL but were not assessed for 1,25$(OH)_2D_3$ sensitivity. In a recent study, global deletion of optineurin in mice altered type 1 interferon signaling and resulted in increasing bone resorption and bone lesions resembling Paget disease.[128] Targeting the *MVNP* gene to cells of the osteoclast lineage in transgenic mice produced bone lesions in the vertebrae similar to those of Paget disease.[123] Transgenic mice coexpressing both MVNP and the *SQSTM1/p62P394L* mutation developed a particularly severe form of Paget disease.[122] The first animal model to examine the mechanism of increased bone formation in pagetic lesions used transgenic mice that expressed MVNP.[129] It was shown that IL-6 was induced in osteoclasts, which produced an increase in IGF1 expression and enhanced EphB2/EphB4 expression, a likely stimulus of osteoblasts.

There is general agreement that genes play a role in determining susceptibility to developing Paget disease, but family studies clearly demonstrate that a genetic abnormality alone is not sufficient to produce the disorder. Although the role of viruses remains controversial, the observation that Paget disease is less common than in the past, coupled with the fact that measles vaccine first became available 57 years ago, lends further support for a viral role in this disorder.[130]

THE ANATOMY OF THE THYROID GLAND

Gross Anatomy

The thyroid gland was first described by Galen (130–210 A.D.) in his work “De Voce.” The gland was named “thyroid” by Thomas Whorton (1614–1673), due its proximity to the thyroid cartilage. Despite its name (thyreòs in Greek means “shield”; also, the German name “Schilddrüse” means “shield gland”), the characteristic shape of the thyroid, consisting of two lateral lobes connected by a narrow isthmus, is more reminiscent of a butterfly or a capital H than a shield (Fig. 64.1). The lateral lobes are 3 to 4 cm long and 15 to 20 mm wide and are located between the larynx and the trachea medially and the carotid sheath and the sternomastoid muscles laterally. The upper pole of the lobes reaches the level of the thyroid cartilage, while the lower pole reaches the V to VI tracheal ring. The isthmus is 12 to 20 mm long and 20 mm wide and crosses the trachea between the I and II rings. In a normal adult the entire gland is approximately 6 to 7 cm wide and 3 to 4 cm long, and its weight ranges between 15 and 25 g. The thyroid is generally asymmetrical: the right lobe may be twice as large as the left, extending higher and lower in the neck than the left pole. Interestingly, in patients with dextrocardia, the position of the lobes is reversed, suggesting that the asymmetry in the thyroid lobes could be due to the position of the heart. A thin connective capsule encloses the thyroid. Fibrous septa are occasionally detached from this capsule and penetrate into the parenchyma to produce an incomplete lobulation. This inner capsule is connected to an outer capsule (also called the false capsule of the thyroid) that is continuous with the pretracheal fascia. Vessels, the parathyroids, and the recurrent laryngeal nerves are located in the space between the two capsules and are in close contact with the thyroid: the parathyroids on the posterior surface of the gland, and the recurrent laryngeal nerves just medial to the lateral lobes.

Blood Supply

The thyroid is a highly vascularized organ: four arteries provide the gland with an abundant blood supply. Frequent anastomoses among these vessels and an arteriolar network are present on the surface of the gland; from this network, small arteries arborize and enter deeply into the tissue. The capillaries are localized in the interfollicular connective tissue, forming a basket-like network that surrounds each follicle. The capillary endothelial cells are fenestrated, like those of other endocrine glands. Each fenestration is approximately 50 nm in diameter. Stimulation with thyroid-stimulating hormone (TSH) increases the number and density of the fenestrations. The veins emerge from the thyroid parenchyma and form a plexus of three groups of veins: superior, middle, and inferior thyroid veins.

Lymphatics

A rich plexus of lymphatic capillaries surrounds the thyroid follicles and communicates with small lymphatic vessels found in the interlobular connective tissue. These deep vessels give rise to a surface network of lymphatics that drain into several groups of nodes. The uppermost group of nodes is situated just above the thyroid isthmus and is a constant group of one to five nodes called the Delphian nodes. These are readily felt when involved in cancer or Hashimoto thyroiditis. Other variable nodes in the thyroid area include the pretracheal nodes below the isthmus, those on the thyroid surface, and a last group found along the lateral vein, the recurrent laryngeal nerve, or the carotid sheath.

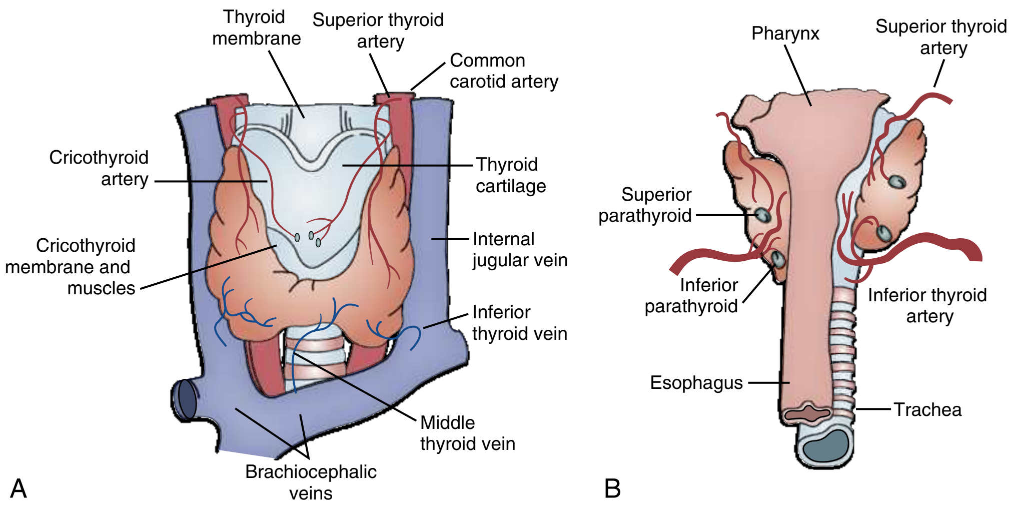

Fig. 64.1 Gross anatomy of the thyroid. A, Anterior view. B, Posterior view.

Innervation

The innervation of the thyroid is provided by sympathetic, parasympathetic, and peptidergic fibers, although few fibers enter the gland. Both sympathetic and parasympathetic fibers extend throughout the tissue among the follicles in close relation to the follicular cells or around a blood vessel.

Some neuropeptides, such as vasoactive intestinal peptide, neuropeptide Y, substance P, or galanin, are exclusively produced in the nerve fibers distributed throughout the thyroid. Presumably, these neuropeptides regulate follicular cell functions via a paracrine pathway. Thyroid innervation is very poor compared to that of other endocrine glands.

Anatomic Variants

The anatomical variants most frequently described in healthy individuals are caused by defects in the regression of the thyroglossal duct. This group of anomalies is generally characterized by the presence of an accessory lobe (pyramidal lobe) attached to the upper part of the isthmus of the thyroid (15% of the population). The pyramidal lobe is a rostral-directed stalk that results from the retention and growth of the caudal end of the thyroglossal duct. Other anomalies are associated with a defective atrophy of the duct. In some instances, the entire thyroglossal duct persists as an epithelial cord connecting the foramen cecum of the tongue to the larynx; in other cases, remainders of the duct form isolated or multiple cysts that are found along the line of descent of the duct. Persistent portions of the thyroglossal duct may differentiate into thyroid tissue and form structures called accessory thyroids. A different developmental defect results in the formation of an ectopic thyroid gland (see later, Late Stages of Thyroid Morphogenesis: Functional Differentiation and Histogenesis). The other frequent anatomical variant (5% of the population) is a thyroid gland that has not developed as a unique mass. These variants include the absence of the isthmus (the thyroid consists of two independent lateral lobes, a physiological condition in nonmammalian vertebrates) or the absence of a significant portion of a lateral lobe, frequently the lower half of the left lobe.

KEY POINTS

- The functional unit of the thyroid gland is the thyroid follicle, surrounded by a network of capillaries. Several of these units make up the thyroid gland. The assembly of the units determines the amount, not the type, of activity.

THYROID FOLLICULAR CELLS AND THYROID FOLLICLES

The thyroid gland displays a peculiar highly-organized architecture characterized by the presence of spheroidal structures known as follicles. The thyroid follicles, supported by an interfollicular extracellular matrix and a capillary network, are composed of a single layer of epithelial cells, the thyroid follicular cells (TFCs), that surround a closed cavity, the follicular lumen, which is filled with colloid, a concentrated solution of thyroglobulin. TFCs represent the largest cell population of the thyroid gland and are responsible for thyroid hormone synthesis. When observed under the light microscope TFCs show a neutrofilic cytoplasm, a basal nucleus, and periodic acid-Schiff–positive vacuoles (phagosomes). Follicular cells appear as cuboidal epithelial cells, whose height is approximately 15 μm. Cells become flatter (squamous) or higher (columnar) depending on whether or not they undergo TSH stimulation. Electron microscopy (Fig. 64.2) reveals the characteristic features of cells actively engaged in protein synthesis, with the rough endoplasmic reticulum and the Golgi apparatus as the dominant organelles in the cell. Furthermore, several vesicles are localized in the apical or subapical cytoplasm. Smaller (150–200 nm) vesicles are exocytotic vesicles containing newly synthesized thyroglobulin. The fusion of these vesicles with the apical plasmamembrane leads to the delivery of thyroglobulin into the follicle lumen. The larger vesicles (500–4000 nm) are filled with dense material, called colloid droplets, and are the result of the uptake of the iodinated thyroglobulin stored in the follicular lumen. The reabsorption of the colloid involves a macropinocytosis mechanism whose first step is the formation of pseudopods at the apical pole. The pseudopods close, and a portion of the colloid is internalized into the cell.

At the molecular level (Fig. 64.3) a follicular cell can be identified by the presence of a specific set of proteins—and the corresponding mRNAs—that are indispensable for its specialized functions. Among such proteins, thyroglobulin and thyroperoxidase are remarkably specific, being detectable exclusively in TFCs. Other proteins, such as TSH receptor (Tshr), sodium/iodide symporter (NIS), pendrin, and Duox/DuoxA complex, though expressed at high level in TFCs, are also present in few other tissues. The exclusive or prevalent expression of genes necessary for thyroid hormone biosynthesis in TFCs appears to be due to a combination of transcription factors unique to this cell type, comprising Nkx2.1 (also called Ttf-1, Titf1, and T/EBP) Pax8, and Foxe1. The molecular features and the functions of these factors will be described in the section on Functional Genomics of Thyroid-Enriched Transcription Factors.

A distinctive feature of follicular cells is their specific polarity (see[1] and references therein). The surface of the cells is divided by the junctional complexes between cells into two functionally distinct but physically contiguous regions: an apical domain that faces the follicle lumen and a basolateral domain orientated toward the extracellular matrix. The apical domain is characterized by the presence of apical microvilli, pseudopods and by the localization of thyroperoxidase, sodium or chloride channels, pendrin, and Duox. The basal domain is characterized by the expression of NIS, Na^+/K^+ ATPase, EGF, and TSH receptor. Thyroid hormone synthesis requires basal to apical transport of iodide and thyroglobulin; conversely, hormone secretion is based on apical to basal transport of thyroglobulin. In addition, the follicular organization allows the biochemical steps required for hormone production (secretion of proteins in the follicular lumen as exocrine cells do; reabsorption and hydrolysis of proteins; release of hormones into blood by endocrine secretion) to occur as a functional chain of events.

In the follicles, thyroid cells form a barrier between the extrafollicular space and the lumen. A tight barrier is critical, because it promotes cell polarity, guarantees efficient transport, and prevents passive back-diffusion. The strong intercellular adhesion is mediated by a junctional complex that consists of tight junctions (zonula occludens), adherens junctions, and desmosomes. All these adhesion structures present the same overall organization: adhesive transmembrane proteins linked to the cytoskeleton by cytosolic adapter proteins. Among the different types of cell junctions, the tight junctions, located close to the apical border of the cells, are the structures that seal cells together. Tight junctions control the permeability of the paracellular space and define the boundary between the apical and basolateral domain of the follicular plasma membrane. They appear as a complex network of anastomosing fibrils consisting of junctional proteins responsible for cell–cell contact. This macromolecular complex interacts with different cellular structures. The major transmembrane proteins in a tight junction are occludin and claudins. The cytoplasmic portion of these proteins interact with intracellular peripheral membrane proteins such as ZO-1 and ZO-2, which link the junction to the microfilaments. The microtubules can also be functionally linked to the tight junctions via cytoskeletal-associated proteins, such as cingulin, 7H6 antigen, and actin.

The anchoring junctions connect the cytoskeleton of a cell to the cytoskeleton of its neighbor or to the extracellular matrix. The epithelial adherens junctions are a type of anchoring junction located below the tight junctions. These junctions are formed by transmembrane proteins, adhesion proteins that belong to the cadherins family (cadherins and transmembrane calcium-dependent adhesion molecules). In thyroid tissue, as well as in other epithelial tissues, E-cadherin accumulates in adherens junctions and plays a central role in the induction of these stable adhesions forming homophilic contacts between neighboring cells. E-cadherin is linked to an intracellular anchor protein, catenin, which in turns binds to the actin cytoskeleton. The catenins participate in intracellular signal transduction pathways, creating a functional bridge that couples physical adhesion to intracellular signaling events. Desmosomal junctions, another type of anchoring junction, are the third type of junction present in epithelia. These structures occur on the plasma membrane below the adherens junction. The transmembrane proteins found in desmosomal junctions are the desmogleins and desmocollins, members of the cadherins superfamily. The cytoplasmic tails of these adhesion proteins bind intracellular proteins (plakoglobin, desmosplakin), which in turn bind to the intermediate cytoskeleton filaments. These protein–protein interactions lead to the formation of a network throughout the tissue that connects different adjacent cells. Follicular cells in the epithelia communicate via the gap junctions. Gap junctions are formed by channel forming proteins (connexins). The channels they form allow inorganic ions and other small water-soluble molecules to pass directly from the cytoplasm of one cell to another, coupling the cells both electrically and metabolically.

Primary cultures of porcine TFCs provided a useful *in vitro* model to understand the mechanisms leading to folliculogenesis. Follicular cells freshly isolated from pig thyroid glands cultured in absence of TSH aggregate only transiently. In presence of TSH, these cells assemble epithelial junctions, polarize, and organize themselves into follicle-like structures in which apical poles of cells delineate a lumen cavity. The first and essential step for *in vitro* folliculogenesis is cell aggregation mediated by E-cadherin. During the first few hours in culture, E-cadherin expression increases in the lateral cell surface and accumulates in the subapical regions, where the adherens junctions will be assembled. The earliest stage of cell surface differentiation is marked by the redistribution of two proteins, ZO-1 and Na^+/K^+ ATPase: ZO-1 is recruited around the future pole of the cell, and the ATPase is confined to the basolateral cell surface. At this stage, apical domain–associated proteins are detected in intracellular vacuoles that later fuse with the cell surface at the nascent apical pole. The follicular lumen is generated in two different steps, both consequences of the polarized phenotype of thyroid cells. The first step is triggered by the lack of adhesive properties of the apical cell surface. A second step, which is required for the control of the follicular size, is driven by a bidirectional ion transport system that secrets chloride in a basal to apical direction and absorbs sodium in an apical to basal direction as well.

The formation and maintenance of follicle-like structures in cultured porcine thyroid cells is dependent on TSH. In absence of TSH, or cyclic adenosine monophosphate (cAMP) stimulators, follicles undergo a morphological conversion: thyroid cells spread and form epithelial monolayers. The activation of the extracellular signal-regulated kinase (ERK) signaling pathway is involved in this conversion. TSH, acting through its second messenger cAMP, inhibits ERK activation and represses the epithelial conversion. In addition, TSH modulates other steps required to maintain follicle organization. Stimulation of cAMP/PKA stabilizes E-cadherin–dependent cell–cell adhesions and inhibits the production of thrombospondin 1, a matricellular protein that is a negative modulator of cell–cell adhesion, thereby inhibiting the dissociation of tight and adherens junctions. Furthermore, TSH downregulates the expression of TGFb1, which induces the loss of epithelial polarization. TSH may also control follicular lumen generation, because chloride channels, located at the apical pole, are regulated by cAMP. One limitation of the data on follicle formation from *in vitro* studies is that they can not be directly extrapolated to comprehend folliculogenesis *in vivo*. Cultured rat follicles invert their polarity and manifest a dramatic change in functional properties unless they are cultured with a gel consisting of extracellular matrix proteins. In addition, TSH is not required for the formation of follicles *in vivo*, because folliculogenesis is not affected in mutant mice with impaired TSH/Tshr signaling (see later, Late Stages of Thyroid Morphogenesis: Functional Differentiation and Histogenesis). Furthermore, follicles in the thyroid gland are surrounded by a basal lamina and present adjacent capillaries, strongly remodeled when iodine uptake is altered, both of which are absent in cultured follicles. As the microvasculature plays a key role in thyroid homeostasis, the angiofollicular unit (AFU), formed by TFCs and capillaries, has been proposed as the functional and morphological unit of the thyroid. Morphological changes in the endothelial compartment in response to iodine deficiency have been described that anticipate by a few days the changes visible in the epithelial cells and are related to vascular endothelial growth factor (VEGF) release from thyroid epithelial cells. Thus, thyroid hormones synthesis will be controlled by both follicular cell homeostatic processes and the vascular plasticity that, in turn, is controlled by TSH plasma levels in a delayed phase.[2] Even if AFUs are able to respond synchronously to goitrogen stimuli, they do not work uniformly, but as heterogeneous clusters of units each presenting its own functional properties, allowing the gland to adapt to fast-changing physiological conditions.

KEY POINTS

- The thyroid follicular cell (TFC) is a highly specialized cell type only found in the thyroid gland. TFCs are characterized by a unique combination of proteins devoted to the synthesis of thyroid hormones and by regulatory factors that control their ontogeny and function.

OTHER THYROID CELLS

In addition to the follicular cells, the thyroid gland is composed of other epithelial cell populations of different origin: i) the parafollicular C cells, devoted to calcitonin production; ii) the epithelial cells, vestiges of the ultimobranchial body; iii) the thyroid stem cells.

C Cells

The other endocrine cells present in the thyroid gland of mammals are C cells, which synthesize and secrete calcitonin, a polypeptide hormone involved in calcium metabolism. In lower vertebrates C cells form an organ called the ultimobranchial gland that is separate from the thyroid gland.

C cells are known as parafollicular cells because of their distribution among follicular cells. But, in spite of their name, C cells are not solely located between follicular cells and the basement membrane (a real parafollicular position), but are also found among the follicles (interfollicular) or in an intrafollicular position. C cells are found dispersed as individual cells closely associated with follicular cells, or in more complex structures consisting of both follicular and C cells. The number of parafollicular cells in the thyroid differs among species. In humans, the number of C cells decreases with age; indeed, the neonatal thyroid has ten times more C cells than the adult thyroid. In the adult gland the C cells represent less than 1% of the follicular cells and are usually distributed in the upper two thirds of the lateral lobe, in an intrafollicular and parafollicular position.

C cells are characterized by clear cytoplasm and small, compact nuclei. Electron microscopy reveals that these contain cytoplasmatic secretion granules that are 100 to 200 nm in diameter. At the molecular level, C cells are identified chiefly by the presence of calcitonin. The calcitonin protein is encoded by *calcitonin/calcitonin-related polypeptide, alpha* (*Calca*) gene, which is capable of expressing, by tissue-specific alternative splicing, three proteins: calcitonin gene–related peptide (CGRP), katacalcin I, and katacalcin II. The splicing of the first three exons to the fourth exon gives rise to an mRNA that encodes for a protein precursor, which is subsequently processed to yield calcitonin and a peptide known as katacalcin I. CGRP and katacalcin II are the products of alternative splicing and are by far less abundant than calcitonin in C cells. CGRP is a 37–amino acid vasoactive peptide with no known effect on calcium metabolism. The embryological origin of the C cells has been investigated in detail (see later, Differentiation of C Cells).

Ultimobranchial Body-Derived Epithelial Cells

In addition to the TFCs and C cells, another cell population has been described in the mammalian thyroid. These cells do not display a clear follicular organization, but form epithelial structures that were called a "second kind of thyroid follicles" or "ultimobranchial follicle"[3] in rodents. The finding that the second kind of thyroid follicles is absent in the avian thyroid (where ultimobranchial bodies never merge with the thyroid) has suggested that they represent remnants of the ultimobranchial body endodermal component. These structures show a notable interspecies differences.[4] In humans, ultimobranchial body remnants are known as solid cell nests (SCNs). SCNs are frequently present in the thyroid gland, preferentially located in the middle and upper third of the lobes. SCNs appear as para- or intrafollicular clusters and cords of epithelial cells clearly separated from the follicles by a basal lamina. SNCs are composed of two cell types: both C cells and "main" cells, the most important cell population of these structures. In most cases, the SNCs are found admixed with another structure, known as "mixed follicle," in which follicular cells and main cells underline a lumen filled with colloid-like material. Main cells are polygonal cells showing squamoid features, with oval nuclei and eosinophilic cytoplasm, lacking intercellular bridges. The molecular phenotype of main cells is peculiar. Indeed, these cells do not express markers of differentiation common to either follicular cells or C cells. It is worth noting that recent studies in mouse embryos have revealed that p63-positive, Nkx2.1-negative cells are present both in the epithelium of the fourth pharyngeal pouch and in the ultimobranchial body, confirming that the SNCs are ultimobranchial body remnants.

Thyroid Stem Cells

Human TFCs have a slow turnover and divide approximately five times over the course of a lifetime. However, in animal models, it has been demonstrated that the thyroid preserves the ability to both regrow and restore follicular organization after severe perturbations, such as severe experimental thyroiditis or partial thyroidectomy.[5] Recently, in a genetically modified mouse model of thyroid injury,[6] significant transient expression of stemness markers such as Nanog and Oct4 was reported after the massive cell death of follicular cells. Then, clusters of thyroid precursor cells appeared, and finally thyroid function was restored.

These phenomena could be explained by the presence of a population of "adult" stem cells (often referred to as "progenitor" cells) capable both of self-renewal and of differentiating into a more mature cell type.

Adult stem cells have been identified in several organs, where they have a role in tissue repair after disease or injury. Although thyroid adult stem cells have been postulated since early 1990s, their presence in the thyroid gland has been receiving firm support only in the last few years.

Side population (SP) cells are a small subset of cells, also identified in the mouse thyroid gland, that are mostly located in the interfollicular space, where they represent less than 1% of the total cells of the gland. SP cells share many features with *bona fide* stem cells, including the expression of stem cell markers Oct4 and nucleostemin, while SCA1 antigen is expressed only in a half of SP cells. Because of their stemness, they do not express detectable levels of thyroid-enriched transcription factors (Nkx2.1, Pax8, and Foxe1) or functional markers (Tg and TPO). In humans, SP cells have been isolated from cultures of thyrocytes obtained from nodular goiters and display a molecular signature that is similar to that of the mouse SP cells. Usually, SP cells undergo tissue-specific differentiation when maintained in culture. Notably, SP cells isolated from normal mouse thyroid stay in an undifferentiated state in culture and are not able to arrange follicle-like structures. In contrast, human SP cells are able to proliferate *in vivo* and acquire the thyroid phenotype in response to TSH. It is unclear whether disparities between mouse and human SP cells depend on different culture conditions or on the different origin of the cells, from normal or goitrous thyroid, respectively.

In addition to SP cells, the main cells of SCNs (see earlier) also display many characteristics of stemness. Indeed, in these cells, genes specific for either thyroglobulin- or calcitonin-producing cells are not expressed, while markers usually detected in basal/stem cells of several multilayered epithelia are present. Furthermore, these cells show an increased expression of Bcl-2, an antiapoptotic protein that is constitutively expressed in TFCs. This molecular signature corresponds to the definition of stem cell and suggests that the main cells of SCNs could be a source of multipotent cells able to differentiate towards hormone-producing cells.

The data summarized earlier seem to suggest that the regeneration of the thyroid could be due to proliferation and differentiation of thyroid stem/progenitor cells suitable of replacing the pool of the disrupted follicular cells. However, even if the evidence for the existence of thyroid stem cells is convincing, we still do not know what the role of these cells is in the physiology and pathology of the gland.

KEY POINTS

- The thyroid contains a minority of other cell types, of which the most relevant are C cells, devoted to calcitonin synthesis.

THE DEVELOPMENT OF THE THYROID GLAND

The adult thyroid gland in mammals is assembled from two different embryological structures. This composite origin reflects the dual endocrine function of the gland. The thyroglobulin-producing follicular cells derive from a small group of endodermal cells of the primitive pharynx (the thyroid anlage), whereas the calcitonin-producing parafollicular cells derive from the endoderm lining the ultimobranchial bodies, transient embryonic structures that are derived from the fourth pharyngeal pouches.

The thyroid anlage and the ultimobranchial bodies migrate from their original sites, reach their final position anterior to the trachea, and fuse to form the definitive thyroid gland. The thyroid follicles derive from the thyroid anlage cells, while the C cells are scattered within the interfollicular space.

Data on thyroid organogenesis in humans are scarce. In contrast, the morphogenesis and differentiation of the thyroid have been extensively studied in animal models, mostly in mice and rats. Studies on patients affected by congenital hypothyroidism with thyroid dysgenesis (CHTD) have confirmed that identical genetic mechanisms are involved in thyroid organogenesis in humans and in mice. Furthermore, as the molecular pathways involved in the formation of the thyroid and in the differentiation of follicular cells are essentially conserved among all vertebrates, the use of zebrafish as a tool for the analysis of thyroid development has also been introduced in the last years.

Here we will describe in detail the morphological and molecular aspects of thyroid development in mice (summarized in Fig. 64.4). These data can reasonably be extended to humans; the known relevant differences will be highlighted.

Specification of the Thyroid Follicular Cells: The Thyroid Anlage and the Thyroid Placode

Gastrulation involves dramatic changes in the overall structure of the embryo, converting it into a complex three-dimensional structure. The anterior and posterior endoderm invaginates, forming two pockets that extend and fuse, generating a primitive gut tube that runs along the anterior-posterior axis of the embryo. The foregut is the most anterior (cranial) region of this tube. The endoderm of the foregut gives rise to a number of cell lineages that eventually form the epithelial components of the thyroid, thymus, lungs, stomach, liver, and pancreas. All organs derived from the gut tube undergo a rather similar process. First, a restricted group of cells differentiate from their neighbors, as can be visualized both by the appearance of specific molecular markers (usually transcription factors) and by the almost simultaneous appearance of a multilayered structure. Subsequently, all organs undergo a morphogenetic process that entails, depending on the organ, proliferation, branching morphogenesis, migration, or a combination of these processes. Finally, each organ forms a specific cellular organization that is directly correlated to the organ function (i.e., follicular organization in the case of the thyroid). The first differentiation step in this process will be called *specification* throughout this chapter, even though the term usually refers to a reversible process; in the case of all organs derived from the gut, it is at present unknown whether the first differentiation event is reversible or irreversible. While the inductive mechanisms by which endodermal cells produce liver, pancreas, and lung cell lineage are beginning to be understood, the events that commit a group of multipotent endodermal cells to a thyroid fate are not known in similar level of detail.

In mice, which undergo a 19.5 day–long gestation period, the first evidence of thyroid specification is the detection of a monolayer of cells (*thyroid anlage*) that differentiate from the surrounding epithelium and simultaneously express the transcription factors Nkx2.1, Pax8, and Hhex at embryonic day (E) 8 to 8.5. It is worth noting that the thyroid anlage can be detected only by the expression of molecular markers. The morphological consequence of thyroid specification is the appearance of a midline endodermal thickening in the ventral wall of the primitive pharynx, the *thyroid placode*. In the mouse, this is visible at E9 to E9.5, and in humans at E22. The thyroid placode is caudal to the region of the first branchial arch that forms the tuberculum impar, the region of the first branchial arch that gives rise to the median portion of the tongue (Fig. 64.4). At this stage the cells of the thyroid placode simultaneously express four transcription factors: Hhex, Nkx2.1, Pax8, and Foxe1.[7] This unique molecular signature hallmarks these cells, which can be called precursors of TFCs (pTFCs), including all developing thyroid cells that do not yet synthesize thyroid hormones. It is widely accepted that TFCs are derived from the endodermal cells of the thyroid anlage.

Any genes relevant in the patterning process of the foregut, such as *Nodal*, members of the *Gata* family, or *Sox* genes could play a role in thyroid specification. As yet, there have been no reports of either cell fate mapping studies or genetically modified mice clarifying the dissection of the early steps of the thyroid specification. Actually, mouse embryos carrying targeted inactivation of genes involved in foregut patterning usually show developmental arrest at stages that preclude the assessment of the thyroid anlage. In zebrafish, Nodal signaling, required for endoderm specification, seems to be specifically involved in the commitment of thyroid fate. Indeed, as a consequence of the impairment of this signaling, endodermal cells form a reduced gut tissue but do not contribute to the thyroid.[8]

It has been reported that signals from cardiac tissue adjacent to the endodermal layer have an inductive role in liver, pancreas, and lung specification. Similarly, endodermal cells could acquire thyroid fate as a consequence of inductive signals from the mesenchyme or from the adjacent mesoderm. The study of the developing thyroid in mice has shown that, at E8.5, the earliest identifiable thyroid anlage appears in close apposition to the aortic sac, the cardiac region that gives rise to the embryonic heart outflow and pharyngeal arteries. This observation suggests that short-range inductive signals from cardiac mesoderm or from the endothelial lining of the aortic sac could have an inductive role to specify undifferentiated endodermal cells towards a thyroid fate. Indeed, in mice, alterations in the foregut have been observed as a consequence of impaired heart development. Consistent with the hypothesis of a role of cardiac tissue in thyroid development are findings showing that cardiac malformations represent the most frequent birth defects associated with thyroid dysgenesis (TD) in humans. Data obtained from zebrafish and other species are proving invaluable for the study of the extrinsic factors (acting outside the pTFCs) that control thyroid specification. In zebrafish, pharmacological upregulation of Wnt/beta catenin signaling during gastrula stage results both in a block of early cardiac mesoderm differentiation and an extreme reduction of Nkx2.4b-positive thyroid precursor cells. The cardiac and thyroid defects are rescued by enhanced BMP signaling. It is worth noting that, both in zebrafish and in mice, BMP4, a BMP ligand, is expressed in cardiac mesoderm adjacent to developing thyroid. The role of cardiac mesoderm in thyroid specification is reinforced by the findings that genetically mutated fishes in which heart formation is blocked display the same thyroid phenotype.[9] Other reports indicate that thyroid specification requires the combined action of BMP and FGF signaling. Both in zebrafish[10] and in chick embryos, pharmacological manipulations of FGF signaling disrupt endoderm patterning along the anterior-posterior axis. Also, in mice it has been demonstrated that FGF signals are required for correct thyroid development; however, these factors appear to play a role after the specification step (see later, Assembling the Gland: Development and Merging of the Ultimobranchial Bodies). Finally, the relevance of both BMP and FGF signaling has received strong support from the finding that these two pathways are required for thyroid lineage specification of embryonic stem cells (see later, Generation of Functional Thyroid Follicles *In Vitro*).

Early Stages of Thyroid Morphogenesis: Budding, Migration, and Lobulation of Thyroid Primordium

As described above, in mice, by E9.5, the thyroid placode first appears as a multilayered epithelium. Shortly after, it forms a bud that, evaginating from the floor of the pharynx, invades the surrounding mesenchyme as an endodermal extroflession close to the aortic sac. Other endodermal organs follow the same developmental pattern as the

In the *middle* is a schematic representation of the different steps of thyroid organogenesis in mouse embryos; on the *left,* the correspondent embryonic stages *(E,* embryonic day) in mice and humans are indicated; on the *right,* relevant sagittal sections of mouse embryos stained with an anti-Nkx2.1 are shown. *Cr,* Cricoid cartilage; *He,* heart; *Ph,* pharynx; *Th,* thyroid; *Tong,* tongue; *Tra,* trachea; *Trun,* truncus arteriosus.

thyroid: an endodermal domain of specified cells, then a pseudostratified epithelium that eventually invaginates to form a bud.

In these early stages of morphogenesis, the expansion of the thyroid placode does not seem to be due to an enhanced proliferation of pTFCs; indeed, these cells show a very low cell proliferation rate as compared with that of the cells of the surrounding endoderm and mesoderm.[2] Other cells from the pharyngeal endoderm could be recruited into the developing thyroid, contributing to the increase of the number of thyroid progenitor cells. At least for some organs, such as the pancreas, it has been demonstrated that the number of the precursor cells determines the final size of the organ. Thus, perturbations of the genetic mechanisms, still unknown, underlying the recruitment of endodermal cells in the thyroid placode could be a cause of a hypoplastic thyroid in the adult.

At E10.5, the thyroid bud has a flask-shaped structure and is still connected to the floor of the pharynx by a thin cord, the thyroglossal duct, a transient narrow channel. One day later, the thyroid bud is visible as a cap-like shape that has migrated caudally into the mesenchyme, losing all connections with the floor of the pharynx (Fig. 64.4). At this stage the developing thyroid begins to expand laterally, the first step of the process that eventually lead to the formation of the two lobes. At E12.5 the thyroid primordium appears as an elongated structure, extended laterally, in contact to the third pharyngeal arch arteries that will participate the formation of the definitive carotid vessels. By E13, the thyroid bud continues its downward relocation into the mesenchyme and approaches the ultimobranchial bodies, which are accomplishing their ventrocaudal migration from the fourth pharyngeal pouch. By E13.5, the developing thyroid, already formed by rudimental lobes connected by a thin central portion, reaches its definitive pretracheal position, where it merges with the ultimobranchial bodies containing the precursors of C cells.

In humans, as described in mice, the thyroid anlage appears as a bud invading the mesenchyme at E26; in a few days it appears as a migrating primordium, connected to the pharynx by the thyroglossal duct that disappears around E37. At this stage the thyroid bud acquires a bilobed shape. The developing thyroid merges with the ultimobranchial bodies by the sixth week and reaches its final position in front of the trachea around the seventh week.[11]

The translocation of TFC precursors to reach the sublaryngeal position is a process that lasts for almost 4 days in the mouse and almost 4 weeks in the human embryo. The mechanisms involved in the movement of the thyroid primordium are still a matter of debate. Because the definitive location of the thyroid gland is rather distant from the site of primitive specification, translocation mostly involves active migration of the precursors. However, other morphogenetic events occurring in the neck region and the remodeling of the surrounding mesenchyme could contribute to the definitive location of the thyroid. The expression of transcription factors such as either Hhex or Pax8, or Nkx2.1, is not sufficient for thyroid migration, while Foxe1 plays a crucial role, because the presence of this factor in the thyroid bud is required to allow the cells to move.[7,12]

In many processes of embryogenesis, such as gastrulation, neural crest migration, and heart formation, cell migration is involved. However, in these processes, migrating cells lose the epithelial phenotype and acquire mesenchymal features. This phenomenon, called epithelial-mesenchymal transition, is hallmarked by an increased expression of N-cadherin and the downregulation of E-cadherin. In contrast, TFC precursors maintain their epithelial phenotype (E-cadherin stays expressed) throughout the entire translocation process and never acquire a mesenchymal identity.[13] It has been hypothesized[14] that TFC precursors could translocate following a model of collective cell migration featured by the presence of migrating cells that remain connected during the movement, even though no conclusive data have been reported.

Once the gland reaches its final location, the two rudimentary paratracheal lobes expand, and, by E15 to E16, the thyroid gland assumes its definitive shape (Fig. 64.4). In the last stages of thyroid organogenesis, the gland increases further in size, probably due to the high proliferation of TFCs.

The genetic basis of the formation of two lateral symmetric lobes (lobulation) is beginning to be understood. When the lobulation process begins, at E11.5, the developing thyroid is in contact with the third pharyngeal arch arteries that will participate the formation of the definitive carotid vessels located most closely to the mature thyroid lobes. Signals originating from adjacent vessels or factors regulating vasculogenesis could instruct the process of lobulation by non–cell-autonomous mechanisms. The study of animal models seems to confirm this hypothesis. Mice deficient in either *Shh* (a key regulator of embryogenesis)[15] or *Tbx1* (a factor regulated by Shh itself)[16] display a disturbed morphogenetic patterning of vessels adjacent to the developing thyroid. In these mutated embryos, as a consequence of the absence of caudal pharyngeal arch arteries, the thyroid bud is never in close contact with vessels, and the lobulation process is impaired: the thyroid fails to separate into two distinct lobes, maintaining the shape of a single tissue mass throughout development. Along similar lines, *ntn1a*-deficient zebrafish embryos present severe cardiac, vascular, and thyroid defects. In these embryos the morphology of developing thyroid is perturbed and shows lateral or anteroposterior expansion. *Ntn1a* (a gene involved in Sonic hedgehog signaling) is not expressed in thyroid precursor cells, but rather in the mesenchyme surrounding the aortic arch arteries. Interestingly, loss-of-function mutation in *netrin-1* (*NTN1*), the human homolog of *ntn1a,* was reported in a patient affected by congenital hypothyroidism (CH) and cardiac defects.[17] Finally, TD is not uncommon in patients affected by DiGeorge syndrome, which is characterized by congenital anomalies of the heart and great vessels.

However, the inductive signals from adjacent tissues must interact with events restricted to the thyroid cells to accomplish the lobulation process. Indeed, thyroid hemiagenesis is very frequent in mice double heterozygous for the null allele of *Nkx2.1* and *Pax8*, genes that are expressed in thyroid precursor cells and are absent in other structures close to the developing thyroid.[18]

Late Stages of Thyroid Morphogenesis: Functional Differentiation and Histogenesis

When the thyroid primordium reaches the sublaryngeal position, TFC precursors accomplish their functional differentiation. Notably, the normal final location of TFCs in front of the trachea is not an essential requirement for functional differentiation, because an ectopic, sublingual thyroid expresses thyroglobulin in both human patients and mutated mice.[12] The functional differentiation of TCFs is hallmarked by the expression of a series of proteins, essential for thyroid hormone biosynthesis, such as thyroglobulin (Tg), thyroid peroxidase (TPO), Tshr, NIS, thyroid NADPH oxidases (Duox proteins), and pendrin. This program requires almost three days, between E14 and E16.5, and results in the differentiation of the thyroid primordium in a functional thyroid gland that is able to produce and release hormones. *Tg* and *Tshr* are expressed by E14[19]; expression of *Tpo* and *Nis,* which encode the two key enzymes involved in the process of Tg iodination, appear one day later, probably because their expression is absolutely dependent on the pathway activated by the binding of TSH to its receptor, Tshr.[20] *Duox* expression appears at E15.5,[21] and finally thyroxine expression by E16.5.[22]

The molecular mechanisms involved in the differentiation of the human thyroid are not much different from those found in mice.

Functional differentiation of TFCs requires almost 3 weeks. It begins after the developing thyroid is located in front of the trachea, at E48, when TFCs express *TG* and *TSHR*, and T4 synthesis is detected at the tenth week.[11]

The binding of TSH to Tshr triggers a signaling pathway that regulates many functions of the thyroid gland in postnatal life. In the mouse embryo, *Tshr* is detected in TFC precursors by E14 to E14.5,[19] when the developing thyroid has reached its final position and *Tg* is expressed. At later stages of development *Tshr* expression increases, and it remains expressed in adult life. The availability of mice that carry mutations in the *Tshr* gene enabled elucidation of the role of the TSH/Tshr signaling during embryonic life.[20] Both $Tshr^{hyt/hyt}$ (carrying a loss-of-function mutation in the *Tshr* gene) and $Tshr^{-/-}$ adult mice[23] display severe hypothyroidism with a hypoplastic thyroid. During embryonic life, in the absence of a functional Tshr, the developing thyroid does not show any alterations in either size or histological structure. However, the expression of both *Tpo* mRNA and *Nis* is strongly downregulated.[20] Thus, TSH/Tshr signaling is required to complete the TFC differentiation program. However, the TSH-induced cAMP pathway is not involved in controlling the growth of the embryonic gland, while this pathway is the main regulator of the growth of the adult thyroid. It is worth noting that the requirements for growth of the embryonic thyroid seem to be different between mouse and human; in the latter, TSH/Tshr signaling during fetal life is necessary for development of the thyroid.[24]

During the process of functional differentiation, the thyroid gland also accomplishes its characteristic histological organization. By E15.5, TFCs start to form small rudimentary follicles, as revealed by the expression of ZO-1, a tight junction marker. At E16.5 the gland displays an evident follicular organization. The histogenesis is complete in late fetal life, E17 to E18: the thyroid parenchyma is organized into small follicles, surrounded by a capillary network, that contain thyroglobulin in their lumens.[2] At birth, the thyroid gland is able to produce and release thyroid hormones, though the regulation of its growth and function by the hypothalamic-pituitary axis is fully active only after birth.[24]

In humans, the establishment of the characteristic histological organization lasts several weeks and can be divided into three phases: the precolloid phase, the beginning colloid phase, and the follicular growth phase, which occur from 7 to 10 weeks, from 10 to 11 weeks, and after 11 weeks of gestation, respectively. In the precolloid phase, small intracellular canaliculi develop as an accumulation of colloid material. These small canaliculi enlarge, and the colloid organizes itself into extracellular spaces. In the last phase primary follicles are clearly visible, and the fetal thyroid is able to concentrate iodide and synthesize thyroid hormones. The human thyroid continues to expand until term, and, contrary to mice, the hypothalamic-pituitary-thyroid axis starts functioning at midgestation.

Genetically modified mouse models have given insights on the genetic mechanisms controlling histogenesis. A fully active Nkx2.1 is required for the formation of follicles. The absence of Nkx2.1 in differentiated TFCs impairs the normal architecture of the thyroid. Along the same lines, a hypomorph Nkx2.1 is not able to support proper organization of TFCs.[25] In addition, normal production of miRNAs is required to maintain a correct thyroid structure.[26]

Coordinated interactions between epithelial thyroid cells and endothelium are involved in establishing thyroid follicles.[2] Thus, both cell-autonomous and non–cell-autonomous mechanisms cooperate to achieve the peculiar morphofunctional structures of the thyroid gland.[27]

Assembling the Gland: Development and Merging of the Ultimobranchial Bodies

In vertebrates, calcitonin-producing cells differentiate from the ultimobranchial body, a structure that derives from the fourth pharyngeal pouch. The ultimobranchial body is a definitive organ in all vertebrates except in placental mammals, where it is an embryonic, transient structure fated to join the medial thyroid bud.

In mice, the fourth pharyngeal pouches are evident for the first time by E10. They appear as a lateral extroflexion of the primitive foregut. Shortly after, the caudal portion of the pouches grows, and at E11.5 the fourth pharynx-branchial duct is pinched off, forming an ultimobranchial body primordium visible as an ovoid vesicle with a lumen lined by columnar epithelium.

By E11.5 ultimobranchial body primordia migrate, and at E13 they appear as solid clusters of cells in contact with the midline primordium of the thyroid. By E14.5 ultimobranchial body cells begin to disperse within the thyroid parenchyma, and 1 day later only remnants of ultimobranchial bodies can be distinguished in the thyroid gland. C cells complete their differentiation program through the expression of a series of proteins according to a precise temporal pattern: the basic helix-loop-helix transcription factor Mash1 is expressed by E12.5; the neuronal markers TuJ1, CGRP, and somatostatin are expressed by E14.5; and 1 day later, Mash1 expression disappears, and calcitonin-producing cells can be detected between follicular cells.

In humans, the development of ultimobranchial bodies is similar to that seen in mice. At E24 the ultimobranchial body primordia appear as an outpouching of the ventral component of the fourth pharyngeal pouch. At this stage, the primordium of parathyroid IV is visible as a dorsal evagination of the same pouch. Some authors describe a transient fifth pouch as the endodermal origin of the ultimobranchial body. Probably the shape of the ultimobranchial body anlage itself, which appears as an incomplete pouch, has generated these different interpretations. By E35 the ventral extroflexion is a long-necked flask still attached to the pharynx; a few days later the ultimobranchial body primordium loses its connection with the pharyngeal cavity, starts its migration, and, at E40, reaches the posterior surface of the median thyroid. A connective layer separates these two buds, which display a different histological organization: the lateral bud is composed of a compact mass of cells, while the median bud is composed of interconnecting sheets of epithelium. Finally, at E55, the ultimobranchial bodies are incorporated with the lateral lobes of the thyroid, and the cells from both structures mix with each other.

A number of intrinsic and extrinsic factors play a role in controlling the development and the merging of the ultimobranchial body. Among the cell-autonomous mechanisms, it is worth noting the essential role of Nkx2.1 for the survival of ultimobranchial body cells, but not for their specification. Nkx2.1 functions are in part dosage-sensitive. Indeed $Nkx2.1^{+/-}$ mice display an abnormal fusion of the ultimobranchial bodies with the thyroid diverticulum. Ultimobranchial body cells are incompletely incorporated into the thyroid parenchyma and remain at the dorsal part of the thyroid lobe. Another factor required for the proper merging of ultimobranchial bodies is Hes-1, a transcriptional repressor expressed in ultimobranchial body cells by E11.5. In the absence of Hes-1, ultimobranchial bodies form but show hypoplasia, as well a 3-day delay in fusion with the medial developing thyroid.[28]

Ultimobranchial defects have been reported in mice carrying mutations in *Hox3* paralog genes. These factors regulate the regionalization of the embryo along its major axes and are also involved in the morphogenesis of several structures. *Hoxa3* is expressed in the pharynx, in the developing thyroid, and in the mesenchymal and endodermal cells of the fourth pharyngeal pouch. In *Hoxa3*-null mice, C cells differentiate correctly, but their number is significantly reduced. In many cases, ultimobranchial bodies fail to fuse with the thyroid bud and remain as bilateral vesicles composed exclusively of calcitonin-producing cells (persistent ultimobranchial bodies). Variable thyroid anomalies are described, including hypoplasia, hemiagenesis, reduction of the number of follicular cells, and absence of isthmus. The phenotype appears more severe

in mice carrying various mutant combinations in *Hoxa3* and its paralogs *Hoxb3* and *Hoxd3*.[29] It is thought that the impaired organogenesis of the thyroid is secondary to defects in the ultimobranchial bodies.

Finally, in absence of Tbx1-dependent signals from the mesoderm, the developing thyroid appears as a hypoplastic single tissue mass.[16] Tbx1 signals are executed by FGF8, whose expression in the mesenchyme surrounding the thyroid is regulated by Tbx1.[30]

Differentiation of C Cells

The ontogenesis and differentiation of C cells was initially studied in birds, using as model chick–quail chimeras.[31] The analysis of this model was taken by the entire community as demonstrating that avian C cell precursors derived from the neural crest colonize ultimobranchial bodies. However no formal proof of the neural crest origin of these cells was reported in mice and humans. Recently, very elegant studies both in the developing mouse embryo and in human cancers have clearly shown that, in these organisms, C cells derive from the endoderm lining the fourth pharyngeal pouches,[32] in agreement with several other lines of evidence pointing in the same direction, such as a common essential role of Nkx2.1 in the development of the thyroid proper and of the ultimobranchial body. It would be now essential to revisit the chick–quail chimera studies in order to evaluate whether some details of those studies could be reinterpreted in order to definitively assess whether the same anatomical structure could have different embryonic origins in diverse organisms.

KEY POINTS

- The thyroid gland derives from progenitor cells located mostly in the middle of the pharyngeal cavity, in the area that will be covered by the tongue. Subsequently these cells migrate to reach the final location of the thyroid in front to the trachea. Hence, the sublingual thyroid is a block in normal thyroid development.
- The calcitonin-producing C cells reach the developing thyroid via two lateral pouches emanating from the primitive pharynx. At variance from what believed up to now, it has been demonstrated, at least in mice and men, that they are of endodermal origin, as are the follicular cells.

MOLECULAR GENETICS OF THYROID GLAND DEVELOPMENT

The discovery of transcription factors, which regulate the expression of follicular cell specific genes in the mature thyroid and are also expressed in the thyroid primordium, offered a useful tool to explore the genetic basis of the developmental process of the thyroid gland. At E8.5 epithelial cells fated to become TFCs are unequivocally individualized in the endodermal layer of the primitive pharynx by the expression of *Nkx2.1,*[19] *Foxe1,*[33] *Pax8,*[34] and *Hhex.*[35] Although these factors are also expressed in other embryonic tissues, the coexpression of all four is only seen in both precursor and differentiated TFCs. Experiments in animal models have conclusively demonstrated that the expression of *Nkx2.1*, *Foxe1*, *Pax8,* and *Hhex* is required for the development of the thyroid.[36,37] It is worth noting that, in addition to *Nkx2.1*, *Foxe1*, *Pax8,* and *Hhex,* other genes, both thyroid-enriched and ubiquitous, are required to guarantee a correct organogenesis and functions of the gland (Table 64.1). A list of genes that are known (or are candidates) to be responsible for a thyroid defect, mainly as deduced by the phenotype of knockout animals, is presented in Table 64.2. The role that Tshr plays in thyroid differentiation was summarized earlier in the section on Late Stages of Thyroid Morphogenesis: Functional Differentiation and Histogenesis. The functional genomics of this molecule and the consequences of its mutations in the pathogenesis of thyroid diseases will be exhaustively treated in later chapters. In the sections that follow, we will focus on *Nkx2.1*, *Foxe1*, *Pax8,* and *Hhex,* which can be considered hallmarks of differentiated TFCs.

Functional Genomics of Thyroid-Enriched Transcription Factors

Nkx2.1 Nkx2.1 (formerly known as TTF-1 for thyroid transcription factor–1, or T/EBP) is a transcription factor that recognizes and binds to specific DNA sequences via a 61–amino acid–long DNA binding domain called the homeodomain. The homeodomain sequence is conserved from fruitflies to humans. Nkx2.1 was initially identified in a rat thyroid cell line as a nuclear protein able to bind to specific sequences in the *Tg* promoter.

Nkx2.1 is a member of the Nkx2 class of transcription factors and is encoded by a single gene, whose official name is *Nkx2.1* in mice and *NKX2.1* in humans, which are located on chromosome 12 and chromosome 14q13, respectively.[36] The gene is formed by at least three exons that express multiple transcripts. The most abundant is the shorter isoform, a 2.3-Kb mRNA that encodes a 42-kDa protein that is 371 amino acids long in humans; the longer protein has also been detected in the lung. However, the biological relevance of the various proteins is unclear. Functional studies have determined that the homeodomain is responsible only for binding to DNA, while the transactivating activity resides in two domains, N and C, which are localized at the N-terminus and the C-terminus of the protein, respectively. These

TABLE 64.2 Currently Available Mouse Models of Thyroid Dysgenesis and Summary of Known and Potential Genes Involved in the Pathogenesis of the Disease

Stage of Morphogenesis Impaired	Thyroid Phenotype Expected	Mouse Model	Other Candidate Genes	Genetic Defect in Human Diseases

[a]In humans, unlike mice, the abnormal phenotype is detected in heterozygotes.

two domains appear redundant in *in vitro* assays, but could have different functions *in vivo*. In fact, a number of Nkx2.1 interactors have been identified that bind specifically to either the N domain or the C domain. Nkx2.1 is phosphorylated at several serine residues. This posttranslational modification could regulate Nkx2.1 activity. Indeed, a mouse model harboring a mutated *Nkx2.1* allele encoding a protein that could not be phosphorylated showed impaired differentiation of both thyroid and lung.[25]

The expression pattern of Nkx2.1 has been exhaustively studied in rodents. Nkx2.1 is expressed in the thyroid, lung, and brain. In mouse embryos, Nkx2.1 is detected in the developing thyroid as soon as the thyroid anlage is visible (E8.5).[36] Interestingly, Nkx2.1 is present also in the epithelial cells of the fourth pharyngeal pouches forming the ultimobranchial body.[38] In the adult thyroid, Nkx2.1 maintains its expression in both follicular and parafollicular C cells.[39] During embryonic life, Nkx2.1 is detected in the epithelial cells of the developing trachea and lungs, while in adults it is present in bronchiolar epithelial Clara cells and in type II alveolar cells. As for the brain, Nkx2.1 is expressed in some areas of the developing diencephalon, such as the hypothalamic areas and the infundibulum, from which the neurohypophysis develops. Nkx2.1 expression in the adult hypothalamus is faint, but is upregulated before the onset of puberty.[40] In the dorsomedial and lateral hypothalamic nuclei, Nkx2.1 interacts with Sir2, a member of the sirtuin family, to control expression of orexin type 2 receptor (Ox2r), which plays a crucial role in the regulation of aging and longevity in mammals.[41]

In human embryos, the expression pattern of NKX2.1 is similar to that seen in mice, except that NKX2.1 is not detected in the fourth pharyngeal pouches.[42]

The mechanisms that induce the expression of Nkx2.1 in a restricted pool of foregut endodermal cells are still under investigation; data suggest that Nkx2.1 expression is regulated by many transcription factors, such as Sox2, FoxA1, FoxA2, and GATA6. Then, primordial Nkx2.1-positive foregut endodermal cells are induced to adopt a thyroid fate by the combination of FGF and BMP, whereas Wnt and BMP signaling promote lung specification.[43]

Gene-targeting experiments have enabled assessment of the *in vivo* role of this transcription factor. In the absence of Nkx2.1, newborn mice immediately die at birth and are characterized by impaired morphogenesis of both lung and brain, as well as lack of thyroid and of the entire pituitary[44] (Fig. 64.5). In *Nkx2.1*-null newborns, the lungs appear as dilated sac-like structures without normal pulmonary parenchyma.[44] Furthermore, the trachea has a reduced number of cartilage rings and it is not separated from the esophagus.[45] In the case of the brain, alterations in the ventral region of the forebrain are evident.[46] In addition, both neurohypophysis and anterior hypophysis are absent. As a consequence of the lack of signals from the pituitary, the morphogenesis of adrenal glands is impaired too.[44] In *Nkx2.1*-null embryos, the thyroid anlage forms in its correct position, but at an early stage the morphogenesis of the gland is impaired. The thyroid primordium by E10 is hypoplastic; subsequently, it undergoes degeneration, probably due to apoptosis. The ultimobranchial bodies undergo the same process; they form, but degenerate by E12.[38] Hence, Nkx2.1 is dispensable for the initial commitment of both follicular and parafollicular thyroid cells. However, all cell types that will form the thyroid gland require Nkx2.1 for their survival; in the absence of this transcription factor, no thyroid rudiment is detectable. Another mouse strain, in which *Nkx2.1* is disrupted only in the thyroid gland late in organogenesis, presents different phenotypes: either the thyroid follicles appear atrophic, or the thyroid shows a reduced number of dilated follicles.[47] This indicates the requirement of Nkx2.1 in adult life to maintain the follicular structure of the gland.

The transactivating capability of Nkx2.1 has been clearly demonstrated through studies on cultured cell lines. Sequences recognized by Nkx2.1 have been identified in the promoters of thyroid-specific/-enriched genes, such as *Tg*, *TPO*, *Tshr*, and *Nis*, as well as of the lung-specific genes *SP-A*, *SP-B*, *SP-C*, and *CC10*. However, the genetic pathways controlled by Nkx2.1, especially those that are active during organogenesis, are poorly understood.

Because cell proliferation and differentiation are hallmarks of both embryogenesis and cancer, the study of the role of Nkx2.1 in cancerous

In *Nkx2.1*-null embryos, the thyroid primordium is absent. *Thr,* Thyroid; *Tr,* trachea; *Tp,* thymic primordium. (From Kimura S, Hara Y, Pineau T, et al. The *T/ebp* null mouse: Thyroid-specific enhancer-binding protein is essential for the organogenesis of the thyroid, lung, ventral forebrain, and pituitary. *Genes Dev.* 1996;10:60–69.)

cells could provide additional information on the biological functions of this transcription factor. A germline mutation leading to a mutated Nkx2.1 protein (A339V) has been found in patients affected by papillary thyroid cancer (PTC) with a history of mononodular goiter and in their first-degree relatives affected by goiter without PTC.[48] Thyroid cells overexpressing the mutated Nkx2.1 protein display increased cell proliferation, activation of cell cycle regulator genes, and impaired expression of thyroid-specific genes.[48]

Pax8. *Pax8* (paired box gene 8) is a member of a family of transcription factors characterized by the presence of a 128–amino acid–long domain that recognizes and binds to specific DNA sequences. This DNA-binding domain is called a paired domain because it was identified for the first time in the *Drosophila* segmentation gene *paired*. Pax8 was identified in the mouse as a protein expressed in the developing thyroid gland.[34] Further studies demonstrated that the Pax8 paired domain recognizes and binds to a single site present in the *Tg* and in *Tpo* promoters.[49]

The gene encoding Pax8 is located on chromosome 2 in mice,[34] and the human ortholog, *PAX8*, is located on chromosome 2q12-q14. It consists of 12 exons that encode for different alternative spliced transcripts, at least six different transcripts in the mouse and five in humans. All the isoforms generated share the paired domain located near the N-terminus and differ in their C-terminal regions. Pax8a, the most abundant isoform, is a 457–amino acid–long protein in mice[34] and is 450 amino acids long in humans.

Pax8 is expressed in kidneys, in the nervous system, and in the thyroid.[34] In the developing kidney, at an early stage, *Pax8* is expressed in the nephrogenic cord and in mesonephric tubules; then it is present in the cortex of the metanephros, whereas in the adult kidney Pax8 is clearly detected in the medullar zone. In embryos, *Pax8* is transiently expressed in the myelecephalon,[34] in the uterine epithelium, and in the luminal epithelium of the oviduct and vagina. In males, strong *Pax8* mRNA expression was observed in the epithelium of the epididymis.[50]

As for the thyroid, Pax8 is expressed in the TFCs and in their precursors from the early stages of gland morphogenesis.

In humans, PAX8 is detected in the developing thyroid, kidneys, otic vesicle, central nervous system at E32,[42] and in both the luminal and glandular epithelium of the endometrium.[50]

Analysis of *Pax8* $^{-/-}$ mice[51](Fig. 64.6) offers the unique possibility of studying the *in vivo* role of this transcription factor. *Pax8*-null pups are born without any apparent brain or kidney defects. In contrast, the thyroid appears as a rudimental structure lacking TFCs, composed almost completely of calcitonin-producing C cells. The animals are affected by a severe hypothyroidism, show growth retardation, and die within 2 to 3 weeks after birth. The administration of thyroxine to these mice leads to their survival. However, in T4-treated female *Pax8*-null animals, the development of reproductive system is severely affected: the uterus appears as remnants of myometrium lacking endometrial structures, and there is no vaginal opening.[50] In *Pax8*-null embryos, the thyroid anlage is correctly formed, evaginates from the endoderm, and begins to migrate into the mesenchyme. However, by E11 the thyroid bud is much smaller compared to that of wild-type mice. In addition, in the absence of Pax8, other transcription factors, such as Foxe1 and Hhex, are downregulated in thyroid cell precursors.[7] At E12.5, TFCs are not detectable.[51] In *Pax8*-null mice, mature TFCs are absent, making it difficult to understand the role of this factor in the control of adult thyroid function. Another mouse strain, in which *Pax8* is disrupted late in gland development, exhibits severe hypothyroidism, hypoplasia of the gland, and reduced expression of thyroid-specific genes.[52] Thus, animal models point to a double essential role of Pax8 for both the survival and the differentiation of TFCs. It is worth noting that, in the developing thyroid, *Bcl-2*, an antiapoptotic gene, is downregulated in the absence of Pax8.[53]

As to the role of Pax8 in TFC differentiation, it has been well established by many reports. Functional assays have demonstrated that Pax8 is required to activate the *Tpo* promoter, and to a lesser extent the *Tg* promoter and the Nis enhancer.[36] In addition, Pax8 is able to activate expression of *Tg*, *Tpo* and *Nis* at their chromosomal loci.[54] A recent paper[55] indicates that, in primary culture of adult human thyrocytes, TSH-dependent upregulation of thyroid-specific genes (*TG*, *TPO*, *NIS*, *DIO2*, *TSHR*) required the simultaneous presence of *NKX2.1*, *FOXE1*, and *PAX8*. Furthermore, expression of these transcription factors does not required TSH, confirming the finding that mutated mice null for TSH/Tshr signaling do not show a reduced expression of Pax8.[20]

Through exhaustive genomic analyses, many other genes modulated by this factor have been identified, suggesting that *Pax8* can be

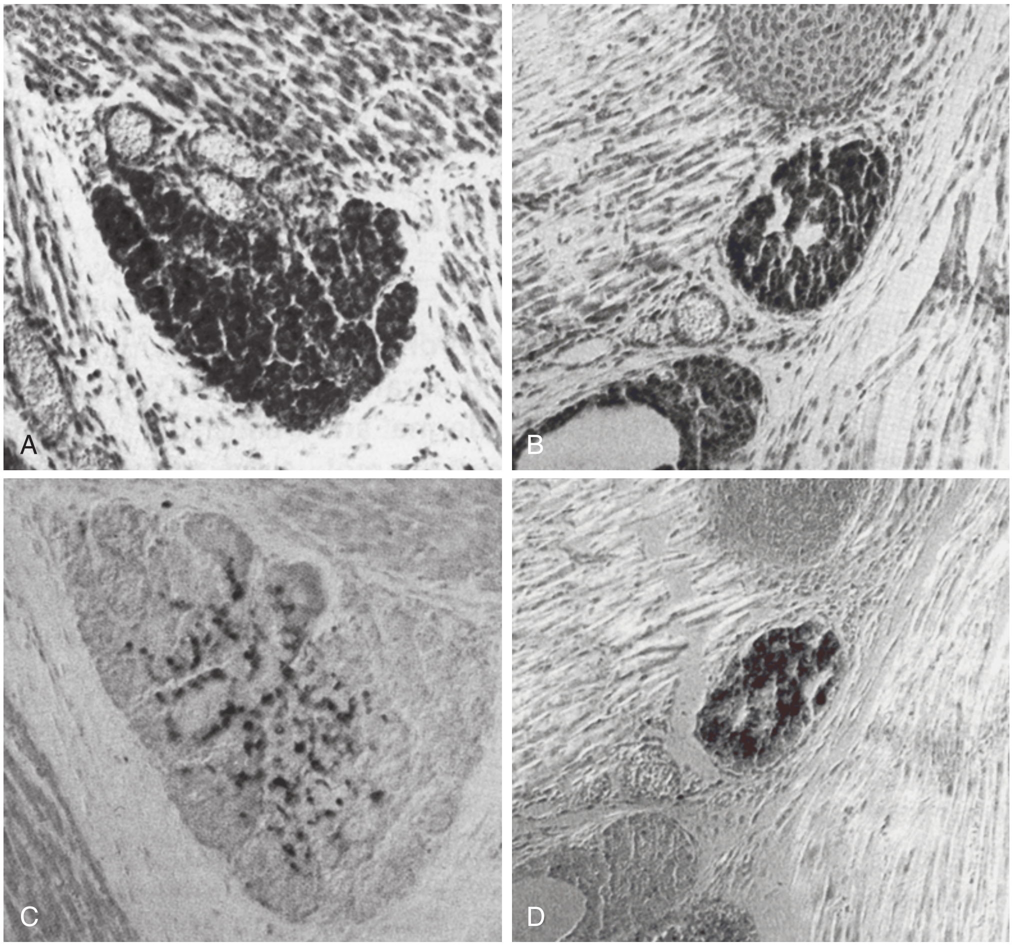

Fig. 64.6 Thyroid gland phenotype in *Pax8*$^{-/-}$ mouse embryos. Sagittal sections of embryonic day 18 wild-type (**A, C**) and *Pax8*$^{-/-}$ (**B, D**) mouse embryos stained with hematoxylin/eosin (**A, B**) and anticalcitonin-specific antibody (**C, D**). The thyroid gland of *Pax8*$^{-/-}$ embryos is smaller than that of wild-type mice and composed almost exclusively of C cells. (From Mansouri A, Chowdhury K, Gruss P. Follicular cells of the thyroid gland require *Pax8* gene function. *Nat Genet.* 1998;19:87–90.)

considered a master gene in both development and differentiation of the thyroid gland.

Foxe1. Foxe1 (formerly called TTF-2 for thyroid transcription factor–2) was originally identified as a thyroid-specific nuclear protein that can bind to a sequence present in both the *Tg* and *Tpo* promoters under insulin, IGF-1, or TSH stimulation. Subsequently, rat *Foxe1* cDNA was cloned, allowing characterization of the salient features of this protein.[33] Foxe1 belongs to the winged helix/forkhead family of transcription factors, which are characterized by a 100–amino acid–long DNA binding domain homologous to that of the *Drosophila forkhead* gene. The official name for the genetic locus encoding this transcription factor is *Foxe1* in mice (located on chromosome 4[33]) and *FOXE1* in humans (located on chromosome 9q22[12]). *Foxe1* is an intronless gene coding for a 42-kDa protein that is phosphorylated.[56] The protein contains an alanine stretch of variable length, ranging from 11 to 22 alanines. In humans, the most frequent *FOXE1* allele contains 14 alanine residues.[57] Interestingly, the presence of 16 alanines seems to be inversely associated with the risk of TD.[58]

Like *Nkx2.1* and *Pax8*, *Foxe1* is detected in the thyroid primordium, and its expression is maintained in TFCs during all stages of development and in adulthood. However, during embryonic life, *Foxe1* has a wide domain of expression. Indeed, at early stages of development, *Foxe1* is detected in the endodermal epithelium lining the primitive pharynx, the arches, and the foregut, as well as transiently in Rathke's pouch. Subsequently, *Foxe1* is expressed in tissues that develop from the pharynx and pharyngeal arches: thyroid, tongue, epiglottis, palate, choanae, and esophagus. In addition, Foxe1 is also detected in the whiskers and hair follicles, which derive from the ectoderm.[56] In humans, *FOXE1* is expressed in the thyroid, foregut embryonic thymus,[42] outer follicular hair sheath, and the seminiferous tubules of prepubertal testes.[59]

Studies in mutant mice have shown that *Foxe1* is tightly regulated in the thyroid bud by Pax8 and in the pharyngeal cells by Shh.[7] In differentiated rat thyroid cell lines, transcription of the *Foxe1* gene is under the tight control of TSH and cAMP, as well as that of insulin and IGF-1.[33] These data suggest that Foxe1 plays an important role in controlling interactions between hormone signaling pathways and thyroid-specific gene expression. In the developing thyroid, these controls do not seem to be effective, because in mutated mice that lack TSH, GH, and IGF-1, the expression of *Foxe1* is not affected.[20]

Analysis of *Foxe1*-null mice (Fig. 64.7) revealed the role of this transcription factor during thyroid development. Targeted inactivation of *Foxe1* showed that homozygous *Foxe1*$^{-/-}$ mice are born at the expected Mendelian ratio but die within 48 hours of birth. These mice display a severe cleft palate, probably responsible for the perinatal death, an absent thyroid or ectopic thyroid, lack of thyroid hormones, and elevated TSH levels in the bloodstream.[12] The early stages of thyroid morphogenesis,

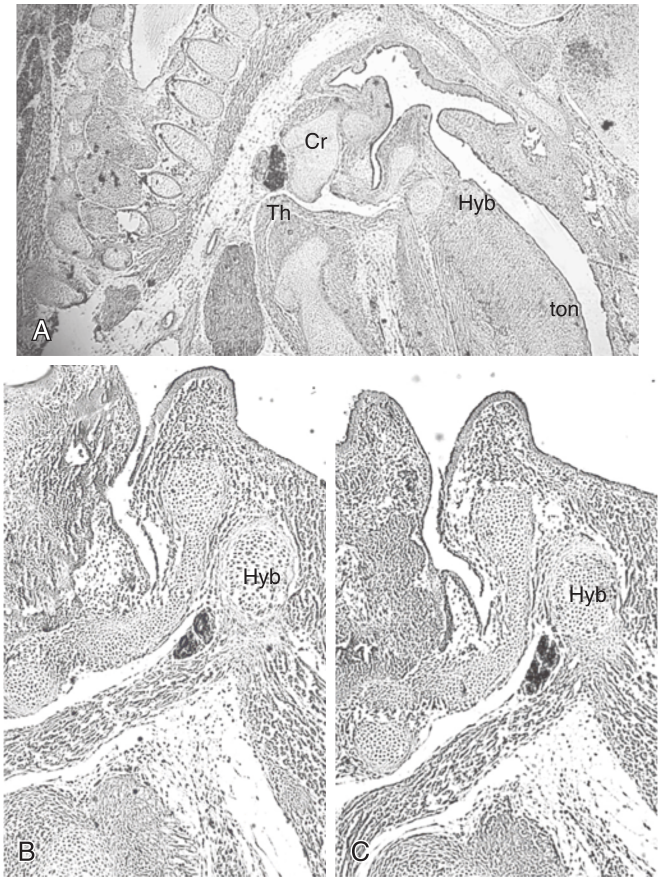

Fig. 64.7 Thyroid gland phenotype in *Foxe1*$^{-/-}$ mouse embryos. Sagittal sections of embryonic day 15.5 *Foxe1*$^{+/-}$ (A) and *Foxe1*$^{-/-}$ (B, C) embryos stained with an anti-*Nkx2.1* (A, B) or antithyroglobulin (C) antibody. The thyroid gland of the *Foxe1*$^{-/-}$ embryo is in a sublingual position. *Cr,* Cricoid cartilage; *Hyb,* hyoid bone; *Th,* thyroid; *ton,* tongue. (From De Felice M, Ovitt C, Biffali E et al. A mouse model for hereditary thyroid dysgenesis and cleft palate. *Nat Genet.* 1998;19:395–398.)

when the thyroid anlage is the formed, are not affected in *Foxe1*$^{-/-}$ embryos. However, at E10 thyroid precursor cells are still on the floor of the pharynx in *Foxe1*-null embryos, whereas in wild-type embryos the thyroid primordium begins to descend towards its final location. At later stages of development, in the absence of Foxe1, TFCs either disappear or form a small thyroid remnant still attached to the pharyngeal floor. In this case, the cells are able to complete their differentiation program, as shown by their ability to synthesize thyroglobulin. These data indicate that during embryonic life Foxe1 has a specific role in controlling the migration of TFC precursors, most likely by controlling the expression of target genes required for the migration process, but is not relevant for the specification and differentiation of thyroid anlage. In addition, Foxe1 could be involved in the survival of TFCs, because in many *Foxe1*-null embryos the thyroid primordium disappears.[7,12]

Recently, a genomic-wide screen performed in *Foxe1*-silenced thyroid cells indicated that both Duox2 and NIS are transcriptional targets of Foxe1.[60]s However, it is still hard to define the functions of this gene in the physiology of the gland, because *Foxe1*-null newborns die at birth.

Hhex. Hhex (formerly known as Hex for hematopoietically expressed homeobox, or Prh for proline-rich homeobox) is a homeodomain-containing transcription factor that was first identified in multipotent hematopoietic cells. It was later demonstrated that Hhex is expressed in other tissues, including the thyroid.[35] Hhex is encoded by a gene called *Hhex* in mice and *HHEX* in humans, which are located on chromosome 19 and chromosome 10q23.32, respectively. The gene has four exons and codes for a protein that is 270 amino acids long. *Hhex* is an orphan homeobox–containing gene, because the sequence of its homeodomain, which is responsible for binding to DNA, shows some differences with respect to other homeodomains. Outside the homeodomain, Hhex contains an N-terminal proline-rich region and a C-terminal acid region. These two regions are probably involved in repressing the transcription of the target genes.

In mouse embryos, *Hhex* is expressed very early in the primitive and then in the definitive endoderm. At E7.0 *Hhex* is detected in the developing blood islands, in the ventral foregut endoderm at E8.5 to E9.0, and in the endothelium of the developing vasculature and heart at E9.0. Hhex is an early marker of thyroid cells, because it is already expressed in the thyroid anlage at E8.5,[35] at the same stage in which *Nkx2.1*, *Foxe1,* and *Pax8* are detected. In the adult, in addition to the thyroid, *Hhex* expression is maintained in liver and lungs.

Analysis of mutated mice has revealed that this factor is absolutely necessary in many developmental processes. *Hhex*$^{-/-}$ embryos die at midgestation (E13.5–E15.5) and show severe defects in liver, forebrain, heart, and thyroid morphogenesis.[61] In *Hhex*-null embryos, thyroid precursor cells are present and express Nkx2.1, Pax8, and Foxe1 until E9. At E10 the thyroid primordium is composed of a few cells that do not express Nkx2.1, Foxe1, or Pax8.[61] Hence, Hhex guarantees the survival of TFC precursors and maintains the expression of Foxe1, Nkx2.1, and Pax8. Studies in differentiated thyroid cells suggest that the network controlling Hhex and the other thyroid-specific transcription factors is complex. *Hhex* seems to be regulated by Nkx2.1,[36] and overexpression of *Hhex* partly inhibits *Tg* promoter activity. These data are consistent with the hypothesis that Hhex is a transcriptional repressor in thyroid cells, as reported in other systems.

Thyroid-Enriched Transcription Factor Interactions. The analysis of the phenotype of *Nkx2.1*, *Hhex*, *Pax8*, and *Foxe1* knockout mice highlights a complex network of reciprocal regulatory interactions among these transcription factors.[7] At an early stage of thyroid development, the initial *Nkx2.1*, *Hhex*, and *Pax8* expression seem to be independent from each other, because the absence of any of these genes does not affect the expression of the others. The expression of *Foxe1*, on the contrary, is tightly controlled by *Pax8*. By E10, in the thyroid placode, each affects expression of the others. *Foxe1* seems to be located downstream in this regulatory network, because it is expressed only if Titf1, Hhex, and Pax8 are simultaneously present, while in *Foxe1*-null mice *Nkx2.1*, *Hhex,* and *Pax8* are correctly expressed in the thyroid bud. Interestingly, in the human thyroid the expression of both *NKX2.1* and *PAX8* precedes the onset of *FOXE1* expression.[42] This genetic cascade has been conserved during evolution. In zebrafish, at an early stage of thyroid development, *hhex*, *nk2.1,* and *pax2.1* (which has a role comparable to murine *Pax8* in the zebrafish thyroid) expression are not dependent on each other, while at a later stage the expression of each gene requires the presence of the other genes.[62]

The network summarized above is due, at least in part, to regulatory interplay at the transcriptional level. *Pax8* is a target of Nkx2.1, and reciprocally, Nkx2.1 is a target of Pax8.[63] The *Hhex* promoter is activated by both Nkx2.1 and Pax8.[64] Finally, autoregulatory loops contribute to maintenance of *Nkx2.1*, *Pax8,* and *Hhex* expression, because each factor stimulates transcription from its own promoter[65] (Fig. 64.8). In addition to the transcriptional network, physical and functional interactions between Nkx2.1 and Pax8 have been demonstrated. Nkx2.1 and Pax8 form a protein complex and cooperate in activating the *Tg* promoter. The cooperation between these two factors

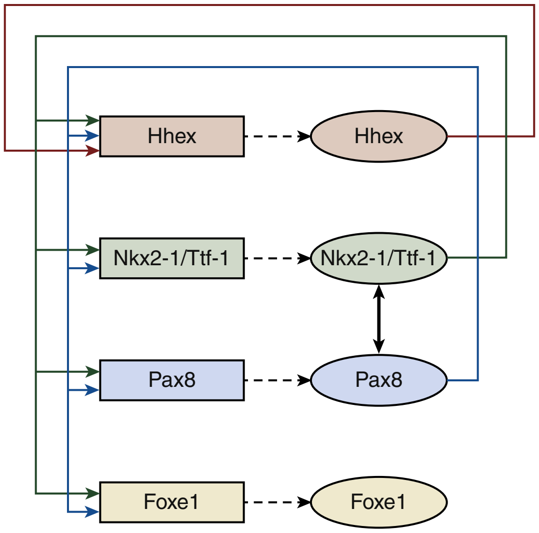

Fig. 64.8 **Physical and regulatory interactions among Hhex, Nkx2.1/Ttf-1, Pax8, and Foxe1.** Factors are represented by *ovals*; gene promoters are represented by *rectangles*. Binding of a regulator to a promoter is indicated by a *solid arrow*. Genes encoding regulators are linked to their respective regulators by *dashed arrows*. Physical interaction between factors is indicated by a *thick line arrow*. (From De Felice M, Di Lauro R. Intrinsic and extrinsic factors in thyroid gland development: an update. *Endocrinology*. 2011;152:2948–2956.)

is confirmed *in vivo*. Actually, double heterozygous mice for the null allele of *Nkx2.1* and *Pax8* show severe hypothyroidism characterized by thyroid hypoplasia,[18] although *Pax8* or *Nkx2.1* single heterozygous null mice do not show defects in thyroid morphogenesis.

The extreme relevance of the functional interaction between these two proteins has received strong support by the finding that aggregated mouse embryonic stem cells overexpressing both *Pax8* and *Nkx2.1* form thyroid follicular organoids that express thyroid-specific genes[66] (see later, Generation of Functional Thyroid Follicles *In Vitro*).

From Animal Models to Human Diseases

Eighty-five percent of cases of CH, the most frequent endocrine disorder in newborns, are due to TD. The term "thyroid dysgenesis" indicates an ectopic or hypoplastic thyroid, as well as the absence of thyroid (thyroid agenesis or athyreosis). Thyroid dysgenesis is due to anomalies during gland organogenesis: defects in growth and/or differentiation of the thyroid primordium can result in an absent or hypoplastic thyroid, and impaired migration of thyroid precursor cells causes an ectopic gland.

The discovery that the disruption of genes involved in thyroid morphogenesis causes impaired development of the gland in mice has led researchers to look for mutations in the homologous human genes in patients affected by CHTD. These studies have been successful, because a minority of cases of CHTD are associated with mutations in genes relevant for thyroid development, confirming data obtained in animal models.[11,36] Although these cases account only for a small minority (3%–5%) of cases of CHTD, this finding proves unequivocally that CHTD can be a genetic and inheritable affection due to defects in genes involved in thyroid development. New technologies such as next-generation sequencing have made it possible to identify a number of mutated genes in patients affected by CHTD.[67] However, in many cases the causative role of these mutations has to be confirmed. The genetic landscape of CHTD has been recently and exhaustively reported in a number of excellent reviews.[68]

In this section we will focus only on cases of CHTD associated with mutations in *NKX2.1*, *FOXE1*, and *PAX8* in which a clear pattern of Mendelian inheritance can be observed. The integration of these studies with data obtained from animal models played a valuable role in providing insights into the molecular mechanisms that underlie normal and pathological thyroid development.

Thyroid Dysgenesis. Both athyreosis and agenesis indicate the absence of thyroid tissue. However, agenesis should be used to define the absence of the gland due to a defective initiation of thyroid morphogenesis.[36] The term athyreosis indicates a dysgenesis characterized by the disappearance of the thyroid due to alterations in any step following the specification of the thyroid anlage. In several patients with athyreosis, the presence of cystic structures, probably resulting from degeneration of the TFC clusters, suggests that thyroid specification was not impaired in these subjects. At the moment, there are no animal models that display a *bona fide* agenesis. Indeed, gene-targeting experiments have demonstrated that Nkx2.1, Foxe1, Pax8, and Hhex do not play a role in specification of the thyroid anlage, which forms correctly in embryos deprived of any of these proteins. Agenesis could be due to defects in genes involved in the early regionalization of the endoderm, including the genes controlling the onset of *NKX2.1*, *FOXE1*, *PAX8*, and *HHEX* expression. However, the relevance of these genes in CH is difficult to demonstrate, because mutations in genes that are widely expressed in the endoderm at early stages of development could cause embryonic-lethal phenotypes and/or many additional defects. On the contrary, the knockout mice described in the previous section are good models of athyreosis. In these mutants, the morphogenesis of the gland begins, but the thyroid bud disappears, probably due to a defective survival program or due to proliferation of the precursors of the follicular cells.

Thyroid hypoplasia (a gland containing a reduced number of follicular cells) is probably a genetically heterogeneous disorder and could be a consequence of alterations in any of the steps that control the expansion and/or survival of thyroid cells during organogenesis. Genes involved in early stages of development (*NKX2.1*, *FOXE1*, *PAX8*, and *HHEX*), as well as in the late steps, could be good candidates for this dysgenesis. Indeed, mutations in *NKX2.1*, *PAX8*, or *FOXE1* have been found in patients with CH associated with hypoplasia.

The Ectopic Thyroid is a Consequence of an Impaired Thyroid Bud Migration. Familial cases of TD have been described, in which affected members show either ectopic thyroid or athyreosis. This observation raises the possibility that athyreosis and thyroid ectopy have a common underlying mechanism. This hypothesis is consistent with the data from mice lacking the Foxe1 protein, which show either ectopy with a very small thyroid or no thyroid at all.[12]

Thyroid-Enriched Transcription Factors and Thyroid Dysgenesis. Consistent with its expression pattern, mutations have been found in *NKX2.1* in patients affected by brain-lung-thyroid syndrome (OMIM 610978), a complex syndrome characterized by thyroid alterations, choreoathetosis, and lung abnormalities.

All affected *NKX2.1* individuals are heterozygous for the mutation; patients carrying loss-of-function mutations in both alleles have never been reported. It is probable that such a condition would be not compatible with the life, like the corresponding *Nkx2.1*-null mice. After initial reports of two patients with a large chromosomal deletion that includes the *NKX2.1* gene,[69,70] the first mutations were identified several years ago.[71] Until now many different mutations have been identified, including chromosomal deletions and point mutations, with the latter mainly resulting in either truncated proteins or proteins with impaired DNA binding and transactivation properties.[56] In mice, *Nkx2.1* functions are partially dosage-sensitive. Indeed, functional studies have revealed that $Nkx2.1^{+/-}$ mice present decreased coordination and mild hyperthyrotropinemia.[72] According to this finding, the dominant effect of *NKX2.1* mutations in humans could be due to a haploinsufficiency.

NKX2.1$^{+/-}$ subjects display a highly variable phenotype. The classic triad, brain-lung-thyroid syndrome, is not always present. Furthermore, the severity both of chorea and of respiratory symptoms varies largely.

As to thyroid alterations, these have not been reported in many patients; in other cases, patients show elevated TSH levels with mild or severe hypoplasia of the gland or athyreosis, albeit in a minority of cases.[73] There is no clear correlation between the phenotype severity and the type of mutations. A variable phenotype has been described also in the same familial cluster; in addition, it has been reported that a pair of monozygotic twins carrying a loss-of-function mutation at the splice consensus of intron 2 of *NKX2.1* gene are strongly discordant for thyroid phenotype.[73] Actually, one twin showed hemiagenesis of the gland and mild hypothyroidism, while the other twin presented a severe hypothyroidism and athyreosis. Taken together, these data suggest that modifier genes and epigenetic mechanisms could be responsible for the incomplete penetrance and variability of the phenotype.

Mutations in *PAX8* associated with sporadic and familial cases of CHTD were reported for the first time in the late 1990s.[74] By now, more than 50 variants have been reported,[75] especially in the exons coding the DNA-binding paired domain. In only a few cases, missense or truncating mutations in the sequences encoding for C-terminus of the proteins have been described. *In vitro* studies have demonstrated that some of these mutations impair PAX8–NKX2.1 interactions, which are required for synergistic activation of thyroid-specific genes such as *TPO* and *Tg*.[76]

While *Pax8*$^{+/-}$ mice display a normal phenotype,[51] all but one patient reported until now are heterozygous for the mutations, and in the familial cases the mode of inheritance is dominant. Thus, in humans, both fully functional *PAX8* alleles are necessary for correct thyroid morphogenesis, and haploinsufficiency could cause CHTD. In the majority of cases, the mutated protein shows diminished transactivation ability due to loss of DNA-binding capability. In the case of proteins transcriptionally inactive but still able to bind the target sequences, the diminished transactivation capability has been attributed to an impaired synergy with the coactivator p300 or NKX2.1 in activating thyroid-specific promoters.

In most cases *PAX8* mutations are associated to nonsyndromic CHTD. However, some patients display other defects, such as unilateral renal hemiagensis or abnormalities in the urogenital tract.[77] In two cases, deletions encompassing *PAX8* were associated with hypothyroidism and Mullerian agenesis.[78]

The thyroid phenotype is variable, ranging from a normal-sized gland to a severe hypoplasia and even athyreoisis. Because the phenotype shows discrepancy even in familial cases in which related individuals carry the same mutation, effects of other modifier genes could be hypothesized. In some patients, morphological and functional defects of the thyroid become evident only after birth, and overt hypothyroidism develops some years later.[79,80] This finding demonstrates that, in the postnatal thyroid, the survival and proliferation of the follicular cells require a full dosage of PAX8.

In accordance with the phenotype of *Foxe1*-null mice, homozygous loss-of-function mutation in the *FOXE1* gene was first reported[81] in two siblings affected by syndromic CH, characterized by athyreosis, cleft palate, bilateral choanal atresia, and spiky hair (Bamforth–Lazarus syndrome[82]). Until now many different mutations have been identified.[68] All affected individuals are homozygous for the mutations, and in the familial cases the mode of inheritance is recessive. The mutations are inherited from heterozygous carrier parents, apart from a case in which the mechanism of transmission was uniparental isodisomy.

All identified mutations cause substitutions within the FOXE1 forkhead domain, and the mutated proteins show reduced binding and transcriptional activity. However, a novel gain-of-function mutation of the *FOXE1* gene has recently been reported. Indeed, even if the patient presents features typical of Bamforth–Lazarus syndrome, functional studies show that mutated FOXE1 enhances transcriptional activity at both the *TG* and *TPO* promoters.[83] This finding seems to be consistent with the observation that both *Foxe1*-null[12] and *Foxe1* overexpressing mice[84] present cleft palate, one of the hallmark signs of Bamforth–Lazarus syndrome. The thyroid phenotype associated with *FOEX1* mutations ranges from athyreosis to severe hypoplasia. Notably, in mice the absence of this factor causes either athyreosis or defects in thyroid migration, while in humans *FOXE1* mutations associated with an ectopic thyroid have not been described.

Generation of Functional Thyroid Follicles *In Vitro*

The large amount of information collected on the molecules involved in the formation of a functional thyroid gland, recapitulated in the previous sections, together with the increasing availability of several types of cells (for brevity here called stem cells, of which there are however different types) capable of differentiation into diverse cell types, prompted several groups to use these cells to try to form thyroid tissue *in vitro*. The first attempts[85,86] showed that it was possible to promote partial thyroid differentiation starting from mouse embryonic stem cells. Even though no thyroglobulin expression was present, and hence no thyroid hormone was formed, the induction of other thyroid differentiation markers in these experiments established the important principle that it was possible to obtain some thyroid features starting from multipotent, nondifferentiated stem cells. Using a different strategy, a more successful attempt resulted in functional thyroid tissue starting from mouse embryonic stem cells in culture.[66] The approach taken involved forced but transient expression of *Nkx2.1* and *Pax8*, followed by TSH treatment and culturing in Matrigel to allow formation of follicular structures. The follicles that formed therein, in addition to expressing the entire set of thyroid differentiation markers (*Tg, TPO, NIS, Tshr,* and *Foxe1*, in addition to endogenous *Nkx2.1* and *Pax8*), were able, when transplanted under the kidney capsule, to rescue the severe hypothyroidism consequent to thyroid ablation by ^{131}I treatment. These stunning results showed both the relevance of basic research in promoting potentially new, revolutionary applications of regenerative medicine, as well as the courage and the perseverance of the researcher responsible. Of course it will take still some time before a patient with CH will be able to do without the daily doses of thyroid hormones, but the path is clear. It should be emphasized that, in the study presenting such results, no additional information was provided on the mechanisms that induce the beginning of thyroid development *in vivo*, because the authors skipped the phase of thyroid commitment that occurs *in vivo*.

A different experimental approach attempted to recapitulate early events in foregut development and from there try to establish functional thyroid tissue. A first set of observations demonstrated that it was possible to obtain foregut endoderm *in vitro* starting from mouse embryonic stem cells, using a combination of growth factors.[87] Based on those observations, a differentiation protocol was set up that resulted in functional thyroid follicles capable of rescuing severe hypothyroidism in mice.[88] These results also provide important data on the essential role of combined FGF and BMP signaling in promoting very early phases of thyroid specification.

KEY POINTS

- Normal development of the thyroid gland requires a set of regulatory molecules (transcription factors) whose role has been firmly assessed in animal models. A few patients with mutations in these transcription factors show associated thyroid dysgenesis, thus demonstrating that congenital hypothyroidism can be a heritable condition, even though this is only true for a very small number of cases.
- Functional thyroid cells organized into follicles have been recently obtained *in vitro*. The cells are able to rescue severe hypothyroidism in mice, opening the way to a replacement therapy based on cells for the lack or severe reduction of thyroid tissue.

PHYLOGENESIS OF THE THYROID GLAND

The morphological bases of thyroid function are the same in all vertebrates, as reflected by the conserved follicular structure throughout vertebrate evolution. On the contrary, the gross anatomy of the thyroid gland is different in the vertebrate classes. In placental mammals, and in some reptiles, the thyroid is composed of two lobes connected by an isthmus that crosses the trachea. In nonplacental mammals, birds, and amphibians, the thyroid consists of two isolated lobes. In cartilaginous fish and in some teleosts (mostly marine ones), the thyroid is massed into a compact organ. In the remaining marine and almost all freshwater teleosts, the thyroid consists of non-encapsulated follicles scattered in the subpharyngeal connective tissue. Often, heterotopic follicles are found in nonpharyngeal areas such as the kidneys, heart, esophagus, or spleen in these animals. Interestingly, the ability of thyroid cells to proliferate in these ectopic areas has been shown to be genetically controlled in platyfish, and low iodine intake represents a strong inductive stimulus towards this condition. Even though iodine-concentrating activity and iodamino acid production are ancient phenomena that have also been described in nonvertebrate animals, only cyclostomes (such as the lamprey) have a *bona fide* thyroid characterized by follicles scattered in the subpharyngeal connective tissue.

The ontogeny of the thyroid follows the same pattern in all vertebrates, including teleosts[89]: the thyroid anlage arises from an outpouching of the primitive pharynx, migrates caudally, and reaches its definitive position. The development of the thyroid in cyclostomes follows a different pattern from that used by the higher vertebrates. Thyroid follicles in the adult lamprey derive from the endostyle, an organ present only during larval life. In the larval lamprey, at the early stages of development, the endostyle forms as a ciliated groove in the ventral part of the pharynx. During development the groove becomes a cylinder and then a complex structure connected to the pharyngeal cavity by the ductus hypobranchialis.[90] The epithelium of the endostyle differentiates into different types of cells, a group of which displays the ability to trap iodine, exhibits peroxidase activity, and expresses thyroxine.[91] These cells are fated to become “typical” follicular cells only after metamorphosis. A structure similar to the lamprey endostyle is present in the ventral pharynx of protochordates such as cephalocordates (amphioxus) and urochordates (such as ascidians). This organ, which is also called endostyle, is composed of different cell types, the majority of which are involved in the food capturing process.[90] More than a century ago, the homology between the cyclostome endostyle and the thyroid suggested the hypothesis that the endostyle of protochordates was a primitive antecedent of the vertebrate thyroid gland.[92] This hypothesis, based on morphological observation, has gained support from the presence of iodine trapping, thyreoperoxidase activity, and *Ci-Duox*[93] (the *Ciona* homolog of the vertebrate *Duox*) in a group of cells of the endostyle of protochordates. Thus, these cells can be considered “protothyroid” cells.[90]

The molecular mechanisms involved in the differentiation of thyroid cells of mammals are conserved throughout the evolution of protochordates to vertebrate chordates. In urochordates, (*Ciona intestinalis*) the group of cells that express the *TPO* homolog[94] also express *CiFoxE*, a *Foxe1* ortholog,[95] but not *CiNkx2.1*.[96] On the contrary, in amphioxus, both *Nkx2.1*- and *TPO*-homologous genes are coexpressed in the same cells of the endostyle,[97] while the *Foxe1* ortholog *AmphiFoxE4* is not detected in the endostyle, but rather in another pharyngeal-derived structure.[98] Finally, in urochordates, cephalochordates, and lampreys, *Pax2/5/8* (*Pax8* ortholog) is always expressed in the group of cells of the endostyle that exhibit iodide uptake and TPO activities.[99]

These data suggest that, during the evolution of protochordates, a group of genes whose function was to contribute to the specification of the anterior part of the gut were selected as part of the genetic program that leads to thyroid specification. In particular, *Pax8* and its ortholog gene could have had a specific role in the genetic mechanism controlling the differentiation of both protothyroid and true follicular cells, revealing a specific master gene of thyroid cells.

INTRODUCTION

Thyroid-stimulating hormone (TSH, also known as thyrotropin) is the pituitary hormone that is the major regulator of the thyroid gland, and because of this, is a key player in the hypothalamic-pituitary-thyroid axis that regulates thyroid metabolism overall (Fig. 65.1). TSH acts to control cell function by binding to specific cell-surface receptors. Its major physiologic function is mediated by TSH receptors (TSHRs) on the thyroid gland, where it stimulates the production of the thyroid hormones L-thyroxine (T_4) and L-triiodothyronine (T_3). They act on multiple organs and tissues to modulate many metabolic processes, as well as to cause negative feedback inhibition of TSH synthesis and secretion from the pituitary.

TSH is a glycoprotein produced by the thyrotrope cells of the anterior pituitary gland. TSH, luteinizing hormone (LH), and follicle-stimulating hormone (FSH), as well as chorionic gonadotropin (CG) in the placenta, are heterodimers consisting of two noncovalently linked subunits, α (glycoprotein hormone α, GPH α) and β (TSH β) (Fig. 65.2). The α-subunit is common to all four glycoproteins hormones (GPHs), whereas the β-subunit is unique to each and confers specificity of action. Glycoprotein hormones are cystine knot proteins.

Each TSH subunit is encoded by a separate gene and is coordinately transcribed and regulated mainly by hypothalamic thyrotropin-releasing hormone (TRH) stimulation and thyroid hormone feedback inhibition. Production of bioactive TSH involves a process of cotranslational glycosylation and folding that enables dimerization between the nascent α- and β-subunits. TSH is stored in secretory granules and is released into the circulation.

In recent years, it has become evident that TSH receptors (TSHRs) are expressed on a number of extra-thyroidal tissues also. Most prominently, TSHRs that are expressed on cells in the retroorbital space, with a so far unknown physiological relevance, but are involved in the pathogenesis of thyroid eye disease (TED, also termed Graves ophthalmopathy or Graves orbitopathy; see Chapter 72).

REGULATION OF THYROID-STIMULATING HORMONE BIOSYNTHESIS

TSH biosynthesis is regulated by coordinated signals from the central nervous system and feedback from the peripheral circulation. The most important positive input for TSH biosynthesis is hypothalamic TRH, and the most powerful negative regulator is circulating thyroid hormones. However, additional hypothalamic factors and circulating hormones provide important modifying effects. Most of these factors have independent effects on the biosynthesis of the two subunits of TSH (Fig. 65.1).

Hypothalamic Regulation of Thyroid-Stimulating Hormone Subunit Biosynthesis

TRH is a tripeptide secreted from the paraventricular nucleus (PVN) of the hypothalamus and transported to the pituitary via the hypothalamic-hypophyseal portal system, and is a major activator of TSH production, with a marked increase on the transcription of both TSH β- and α-subunit mRNAs[1] (Fig. 65.1). Although TRH may not be required for normal thyrotrope development during ontogeny, TRH appears required for the postnatal maintenance of TSH activation.[2]

TRH binding to a specific membrane receptor, TRHR, on thyrotropes initiates a cascade of intracellular events. TRHR is a member of the class A family of the G protein-coupled receptor (GPCR)

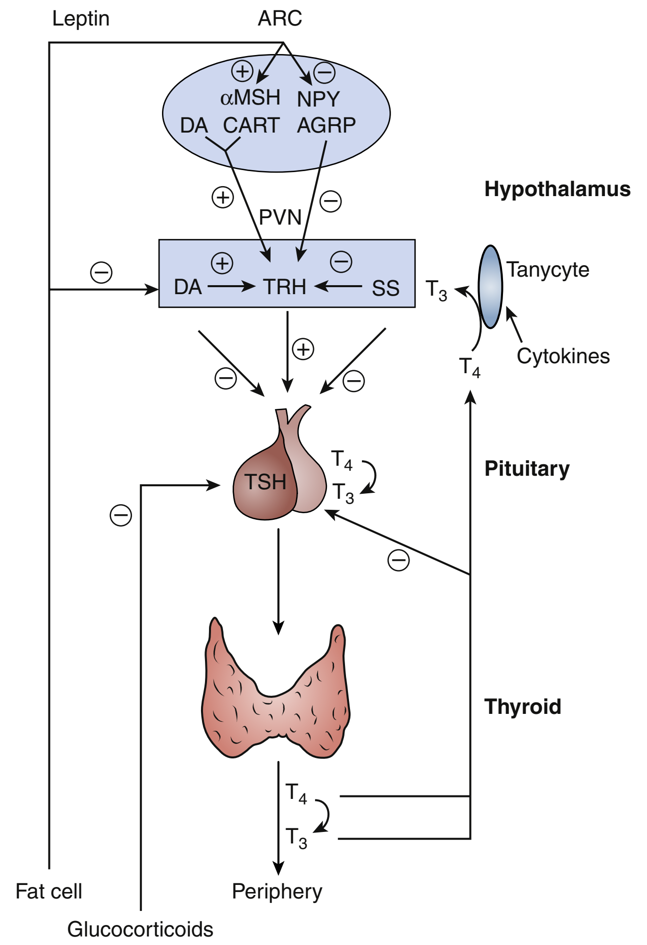

Fig. 65.1 **Neuroendocrine and peripheral control of thyroid-stimulating hormone (TSH) secretion.** Positive and negative stimuli are indicated at various levels within the hypothalamic-pituitary-thyroid axis. *AGRP*, Agouti-related protein; *MSH*, melanocyte-stimulating hormone; *ARC*, arcuate nucleus; *CART*, cocaine and amphetamine regulated transcript; *D2*, deiodinase type II; *DA*, dopamine; *NPY*, neuropeptide Y; *PVN*, paraventricular nucleus; *SS*, somatostatin; *T_3*, triiodothyronine; *T_4*, thyroxine; *TRH*, thyrotropin-releasing hormone. superfamily. Intracellular signal transduction is mediated primarily by coupling to $G_{q/11}$ proteins. TRH binding results in the activation of phosphoinositide-specific phospholipase C, which stimulates phosphatidylinositol 4,5-P2 hydrolysis to form inositol 1,4,5- trisphosphate (InsP3) and 1,2-diacylglycerol (1,2-DG). These second messengers stimulate increases in intracellular calcium and activation of protein kinase C.[3,4,5] TRHR activation also stimulates calcium/calmodulin-dependent protein kinase[6,7] and mitogen-activated protein kinase.[8] The TRHR has also been shown to couple to G_{i2}, G_{i3}, and to a G_s-like protein that does not activate adenylyl cyclase,[9] and to increase cGMP.[10,11] Thus, TRHR activation signals via several intracellular transduction pathways.

TRH stimulates GPH α-subunit biosynthesis through a distinct further mechanism. A cyclic adenosine monophosphate (cAMP) response element–binding protein that binds to the human α-subunit promoter is important for TRH regulation.[12] This mechanism involves two transcription factors that when stimulated by TRH cooperate to activate α-subunit promoter activity resulting from protein–protein interactions.[13] One factor binds to the α-subunit promoter directly, but the

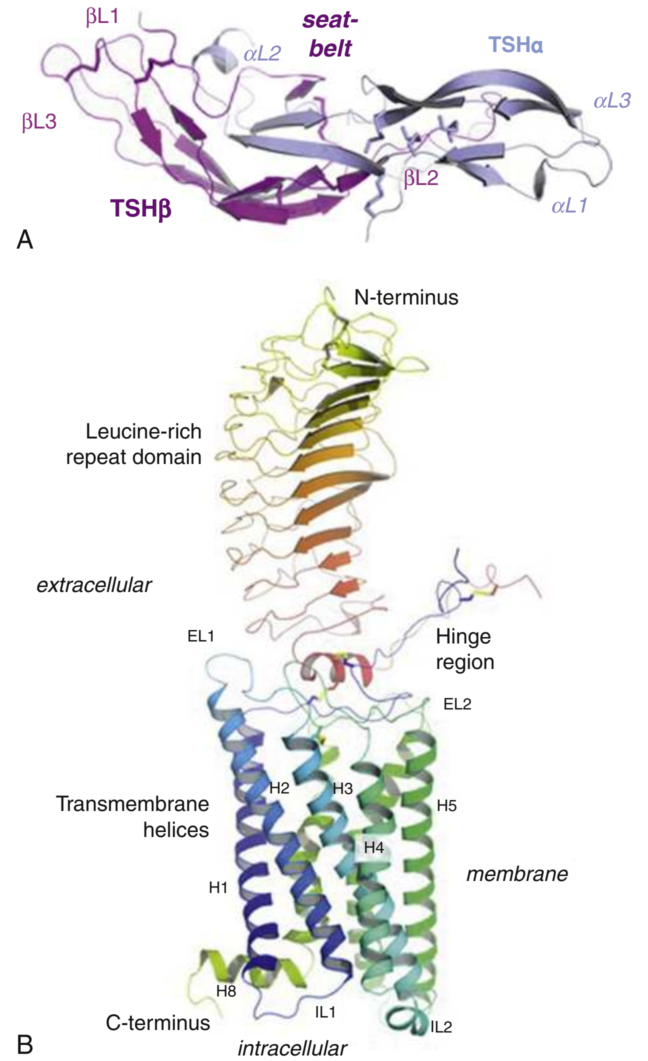

Fig. 65.2 **Structural homology models of human thyroid-stimulating hormone (TSH) and TSH receptor (TSHR). A,** The heterodimeric TSH is constituted by two noncovalently bound subunits, termed alpha-TSH (TSH α) and beta-TSH (TSH β). The human TSH α and TSH β-subunits comprise 116 and 138 amino acids, respectively, and together they form one of the largest endogenous ligands for G protein–coupled receptors known so far. They are intrinsically subdivided into several loop and β-sheet regions according to predicted and observed secondary structures of determined homologous glycoprotein hormones such as follicle-stimulating hormone or chorionic gonadotrophin. The "seat-belt" region is directly involved in TSH binding to TSHR, glycoprotein hormone receptor selectivity, and activity regulation. **B,** The structure of the TSHR comprises 764 amino acids and is subdivided into distinct functional and self-folding units, called domains. In the extracellular domain, the leucine-rich repeat domain (LRRD), with approximately 288 amino acids, is mainly involved in TSH binding. The hinge region with approximately 130 amino acids connects the LRRD with the transmembrane-spanning domain, constituted by seven helices (H1–7) and their interrelated loops, extracellular loops (ELs) and intracellular loops (ILs) 1–3. The hinge region is not a domain by itself because of missing self-folding properties but plays an essential role in the arrangement and function of the entire receptor, in both the ligand-free and ligand-occupied receptor conformations. Each domain or interconnecting structural part plays crucial roles for receptor function, like folding, transport to the cell surface, intermolecular activity (e.g., ligand or G protein binding), or intramolecular functions like signal transduction by structural rearrangements initiated by ligand contacts.

other does not bind DNA, so it must be recruited to the promoter via protein–protein interactions.

Dopamine, acting via DA2 dopamine receptors, inhibits GPH α- and TSH β-subunit gene transcription by, at least in part, decreasing intracellular cAMP.[1] GPH α-subunit gene expression in thyrotropes is inhibited by dopamine, in coordination with the expression of the TSH β-subunit gene.

Peripheral Regulation of Thyroid-Stimulating Hormone Subunit Biosynthesis

Thyroid hormone acts predominantly, if not exclusively, through a classical thyroid hormone receptor (THR) that binds to the upstream region of the β-subunit gene. The thyroid hormone enters the cell via at least four families of membrane transporter proteins and diffuses from the plasma membrane to the nucleus.[14] T_4 serves as a minimally active prohormone that is a substrate for a family of tissue iodothyronine deiodinases, termed DIO1, DIO2, and DIO3. These homodimeric, membrane-bound, selenoproteins can activate (DIO1, DIO2) or inactivate (DIO3) T_4.[15,16] DIO2 is the major T_4-activating deiodinase with a high substrate affinity. It is present on the endoplasmic reticulum close to the nucleus and produces 3,5,3'-triiodothyronine (T_3) by the removal of an iodine residue from the outer ring of thyroxine. Serum TSH levels in normal mice are suppressed by administration of either T_4 or T_3, although only T_3 was effective in the mouse with a targeted disruption of the *DIO2* gene,[17] or in animals treated with the DIO2 inhibitor amiodarone. The observed phenotype of pituitary resistance to T_4 demonstrated the critical importance of DIO2 in controlling negative thyroid hormone regulation of TSH.

TSH β- and α-subunit gene transcription rates are markedly inhibited by treatment with T_3. Studies using mouse TtT-97 thyrotropic tumors have demonstrated that T_3 suppression of TSH β- and α-subunit gene transcription rates, as measured by nuclear run-on assays, is evident by 30 minutes after treatment and is maximal by 4 hours.[18] Other studies using mouse and rat pituitaries along with mouse thyrotropic tumors have demonstrated that steady-state mRNA levels of TSH β- and α-subunit are dramatically decreased by T_3.[19] The mechanism of action of T_3 involves interaction with nuclear THRs that act mainly at the transcriptional level.[20] The T_3 inhibitory effect on the TSH β-subunit gene requires ligand occupied THR, mainly the THRβ1 or THRβ2 isoform, because patients with thyroid hormone resistance and inappropriate secretion of TSH generally have abnormalities in the THRβ gene,[21] although few mutations in the THRα gene have been described (see later).

In general, the mechanism(s) involved in gene upregulation by T_3 are known. THRs bind to cis-acting DNA response elements in the absence of ligand, interacting with a family of nuclear receptor corepressor molecules that recruit histone deacetylases and locally modify chromatin structure to result in repression of the target gene.[22] In the presence of T_3, the corepressor complexes rapidly dissociate and are replaced by coactivator complexes that bind to THRs, increasing histone methylation and acetylation locally on the chromosomal DNA, which unwinds the chromatin.[23]

In contrast, the molecular mechanisms involved in negative T_3 regulation, including that of TSH subunit genes, have not been as well characterized. Liganded THRβ has been reported to recruit histone deacetylase 3 and to reduce histone H4 acetylation, which modifies histones and results in a fully repressed chromosomal state of the TSH β-subunit gene.[24] For the human TSH α-subunit gene, a corepressor complex containing TSH β-subunit was shown to bind the promoter and to determine the basal level of histone acetylation and transcription in the absence of T_3. In the presence of T_3, the complex was released from the THR.[25] Although thyrotrope cells contain all THRs (THRα1, THRβ1, and THRβ2), as well as a non–T_3-binding variant α2,[26] it is THRβ2 that is expressed predominantly in the pituitary[27] and is most critical for the regulation of TSH.[28] Binding studies using chromatin immunoprecipitation assays in TαT1.1 thyrotrope cells showed that THRβ, and not THRα, could interact with the TSH β-subunit promoter. Furthermore, depletion of only THRβ and not THRα abolished T_3-mediated downregulation of TSH β-subunit transcripts.[29] THR accessory proteins, such as retinoid X receptor (RXR), may also bind to DNA[30] and constitute heterodimeric complexes with THR that have different affinities for specific DNA sequences and different functional activities. A particular RXR isoform, RXRγ1, is uniquely expressed in thyrotropes and appears to mediate the inhibition by 9-*cis*-retinoic acid.[31]

Because thyroid hormones can act at the level of both the pituitary and the hypothalamus to regulate TSH, studies were performed to establish their relative contributions. Using genetic knockout mouse models where either TRH or THRβ genes alone, or both together, were eliminated showed a dominant role for TRH *in vivo* in regulating the hypothalamic-pituitary-thyroid axis. The hypothalamic TRH-producing cells are absolutely required for both TSH and thyroid hormone synthesis and control the set points in the hypothalamic-pituitary-thyroid axis.

Thyroid hormone inhibition of α-subunit gene transcription is observed in thyrotropes in coordination with that of the TSH β-subunit. T_3 inhibition may be mediated by different isoforms of the THR[32] in combination with corepressors.[33] It has been suggested that mutations of the T_3 response element of the human α-subunit promoter that eliminate THR binding do not abrogate the inhibitory effect of T_3, suggesting that protein–protein interactions may be more important than protein–DNA binding.[34]

Regulation of Thyroid-Stimulating Hormone Glycosylation

Glycosylation of both TSH subunits is a regulated process that is primarily modulated by TRH and thyroid hormone.[35] Primary hypothyroidism[36] and TRH administration[37] have been found to increase oligosaccharide addition, which results in an increased bioactivity of TSH.[38] The same was noted in patients with resistance to thyroid hormone.

TSH glycosylation patterns were also found to differ in several pathological states, such as central hypothyroidism,[39] TSH-producing pituitary adenomas, and euthyroid sick syndrome.[40] Also observed were changes in the sulfation and sialylation of the oligosaccharide residues, which modulate bioactivity.[41] Thyroid hormone was shown to increase TSH bioactivity via decreased sialylation.[42]

KEY POINTS

- Thyrotropin-releasing hormone (TRH) is the major activator of thyroid-stimulating hormone (TSH) production, and circulating thyroid hormones are negative regulators of TSH synthesis. Thyroid hormones can act at the level of both the pituitary and the hypothalamus to regulate TSH, but the hypothalamic TRH-producing cells are required for both TSH and thyroid hormone synthesis, and control the set points in the hypothalamic-pituitary-thyroid axis.

REGULATION OF THYROID-STIMULATING HORMONE SECRETION

Hypothalamic Regulation of Thyroid-Stimulating Hormone Secretion

TRH from the PVN of the hypothalamus directly affects pituitary TSH secretion *in vivo* (Fig. 65.1). Concentrations that exist in the pituitary portal blood also cause TSH secretion *in vitro*.[43] Immunoneutralization of TRH in animals leads to a decline in thyroid function,[44] and TRH knockout mice have a reduced postnatal TSH surge, followed by impaired baseline thyroid function with a poor TSH response to hypothyroidism. Lesions of the PVN decrease circulating TRH and TSH levels in normal or hypothyroid animals and cause hypothyroidism.[45] Similar results were found in humans with central hypothyroidism.[39] Although baseline levels of TSH are reduced in animals with lesions of the PVN, TSH levels still show appropriate responses to changes in circulating thyroid hormone levels. Thus, TRH may determine the set point of feedback control by thyroid hormones.

Acute intravenous administration of TRH to human subjects causes a dose-related release of TSH from the pituitary. This occurs within 5 minutes and is maximal at 20 to 30 minutes. Serum TSH levels return to basal levels by 2 hours. More prolonged (2- to 4-hour) infusions of TRH lead to biphasic increases in serum TSH levels in humans and animals.[46] The early phase may reflect release of stored TSH, whereas the later phase may reflect release of newly synthesized TSH. An interpretation of TSH responses to even more prolonged TRH infusions is complicated by the increase in serum T_3, which feeds back to further suppress TSH release.[47] Continuous TRH administration *in vitro* also causes desensitization of TSH responses, which may further explain decreased TSH levels with long-term TRH exposure.[48]

Somatostatin (SS) in humans and animals inhibits basal and TRH-stimulated TSH secretion *in vivo* and *in vitro* at concentrations that exist in the pituitary portal blood.[49] In the hypothalamus, the highest concentrations of SS occur in the anterior paraventricular region.[50] From this region, axonal processes of SS-containing neurons project to the median eminence. Animals that have undergone sectioning of these fibers experience depleted SS content of the median eminence and increased serum TSH levels.[51] Similarly, immunoneutralization of SS in animals increases basal TSH levels and TSH responses to TRH.[52] In humans, SS infusions suppress TSH pulse amplitude and abolish the nocturnal TSH surge.[53] Thus, TSH secretion is regulated through a simultaneous dual control system of TRH stimulation and SS inhibition from the hypothalamus.

SS binds to specific, high-affinity receptors in the anterior pituitary gland. Five subtypes of the SS receptor (SST1–5) have been identified,[54,55] and SST2 and 5 have been localized to thyrotropes.[56] Binding of SS to its receptor inhibits adenylate cyclase via the inhibitory subunit of the guanine nucleotide regulatory protein (G_i), which inhibits cAMP production, leading to lowering of protein kinase A activity,[54] and decreases TSH secretion. SS may also exert some effects by cAMP-independent actions on intracellular calcium levels. Hypothyroidism reduces the efficacy of SS in decreasing TSH secretion *in vitro*, which is reversed by thyroid hormone administration.[57] Further studies in mouse thyrotropic tumors indicate that the synthesis of both SST2 and SST5 are markedly downregulated in hypothyroidism and are induced by thyroid hormone.[56] Although short-term infusions of SS lead to pronounced suppression of TSH secretion in humans, long-term treatment with SS or its analogs does not cause hypothyroidism.[58] Growth hormone (GH) deficiency is associated with increased TSH responses to TRH, whereas GH administration decreases basal and TRH-stimulated TSH secretion,[59] possibly as a result of GH stimulation of hypothalamic SS release.

Dopamine also inhibits basal and TRH-stimulated TSH secretion *in vivo* and *in vitro* at concentrations that exist in pituitary portal blood.[60] Exogenous dopamine antagonists, including those that do not penetrate the blood–brain barrier, increase TSH levels.[61] In humans, dopamine infusions rapidly suppress TSH pulse amplitude, do not affect TSH pulse frequency, and abolish the nocturnal TSH surge,[53] whereas administration of a dopamine antagonist results in the opposite effect.[62] Dopamine also has direct effects on hypothalamic hormone secretion that may indirectly impact TSH secretion. For example, dopamine and dopamine-agonist drugs stimulate both TRH and SS release from the rat hypothalamus.[63]

In the hypothalamus, dopamine is secreted by neurons in the arcuate nucleus.[64] From the arcuate nucleus, neuronal processes project to the median eminence. Dopamine acts by binding to type 2 dopamine receptors (DA_2) on thyrotrope cells.[65] This leads to inhibition of adenylate cyclase, which decreases the synthesis and secretion of TSH. TSH may downregulate its own release through the activation of DA_2 receptors on thyrotrope cells.[66] The inhibitory effects of dopamine on TSH secretion vary according to sex steroids, body mass, and thyroid status. Dopamine-antagonist drugs cause greater increases in serum TSH levels in women than in men. Studies show that obesity is associated with enhanced TSH secretion, which may be mediated via blunted central dopaminergic tone.[67] Dopamine inhibition of TSH release is greater in patients with mild hypothyroidism than in normal subjects, although subjects with severe hypothyroidism may be less responsive.[68] Although short-term infusions of dopamine lead to pronounced suppression of TSH secretion, long-term treatment with dopamine agonists does not cause hypothyroidism.

Acute opioid administration in humans may slightly stimulate TSH levels, whereas acute administration of naloxone, an opioid receptor antagonist, has little effect.[69] In contrast to these acute studies, when naloxone is administered throughout the day, 24-hour TSH secretion decreases, primarily because of a decrease in nocturnal TSH pulse amplitude.[70] TSH responses to TRH are also decreased. Serum T_3 levels are decreased as well, suggesting that the magnitude of TSH suppression is sufficient to affect thyroid gland function. These findings suggest that endogenous opioids may play a role in tonic stimulation of TSH secretion.

Peripheral Regulation of Thyroid-Stimulating Hormone Secretion

Thyroid hormones directly block pituitary secretion of TSH.[71] Acute administration of T_3 suppresses TSH levels within hours, whereas chronic administration leads to further suppression. Slight changes in serum thyroid hormone levels within the normal range alter basal and TRH-stimulated TSH levels, confirming the sensitivity of the pituitary gland to thyroid hormone feedback. Thyroid hormones alter tonic TSH secretion and TSH pulse amplitude without affecting pulse frequency, based on findings that subjects with primary hypothyroidism have a near-normal number of TSH pulses, and T_4 replacement leads to a decrease in TSH pulse amplitude without changing pulse frequency.[72]

In addition to direct effects on TSH secretion, thyroid hormones include other actions that impact TSH secretion. At the pituitary level, thyroid hormones decrease the number of TRH receptors[73] and stimulate the activity of the pituitary TRH-degrading enzyme,[74] which act in concert to decrease TRH stimulation of TSH secretion. At the hypothalamic level, PVN TRH mRNA is increased in hypothyroidism and reduced by T_3 and T_4.[75] In contrast, hypothalamic SS content is decreased in hypothyroid rats and is restored by T_3 treatment. Finally, T_3 directly stimulates SS release from hypothalamic tissue[76] and increases the number of SS receptors on thyrotrope cells. These combined effects of thyroid hormones on TRH and SS decrease TRH release from the hypothalamus and indirectly decrease TSH secretion.

Glucocorticoids at pharmacologic doses or high endogenous cortisol levels (Cushing syndrome) suppress basal TSH levels, blunt TSH responses to TRH, and diminish the nocturnal TSH surge in humans and animals.[77] In healthy subjects, infusions of hydrocortisone that increase serum cortisol to levels seen in mild to moderate stress suppress 24-hour TSH secretion.[78,79] Glucocorticoid-induced changes in TSH levels result from decreased TSH pulse amplitude without altering pulse frequency, with more profound suppression of nocturnal TSH secretion and abolition of the TSH surge. Physiologic glucocorticoid levels also affect TSH secretion.[80] Untreated patients with adrenocortical insufficiency can have elevated serum TSH levels that resolve with steroid replacement. Complementary studies of metyrapone (an inhibitor of cortisol synthesis) administration to healthy subjects confirm that endogenous cortisol levels suppress TSH secretion, and physiologic hydrocortisone replacement in patients with adrenal insufficiency decrease daytime TSH levels back to those seen in healthy subjects.

Glucocorticoid suppression of TSH levels may occur directly at the pituitary gland. Animal studies suggest that glucocorticoids exert direct effects on thyrotropes to impair TSH secretion, although these appear to be highly dependent on dose and time-course of administration.[81,82] It does not appear that glucocorticoids directly affect TSH gene transcription. In humans, TSH pulse frequency is maintained during glucocorticoid administration, whereas TSH pulse amplitude is reduced, and TSH responses to exogenous TRH are attenuated, suggesting a direct effect on TSH secretion.

Leptin is primarily a product of adipocytes, although it is also present in thyrotropes. It regulates food intake and energy expenditure, decreasing acutely with fasting in animals and humans.[83,84] Exogenous leptin administration to fed rats raises serum TSH levels, probably by increasing TRH gene expression and TRH release. Similarly, leptin administration to fasting rats or humans reverses fasting-induced decrements in TSH levels, also by increasing *TRH* gene expression and TRH release. This suggests that fasting-related reductions in leptin levels play a role in suppressing TSH secretion. In healthy subjects, leptin and TSH have coordinate pulsatility and circadian rhythms in plasma, with a nadir in the late morning and a peak in the early morning. L-T_4 treatment of patients with subclinical hypothyroidism reduced both serum TSH and leptin levels.[85] In thyroid cancer patients on suppressive doses of levothyroxine, recombinant TSH injections increase serum leptin levels.[86]

Cytokines are circulating mediators of the inflammatory response that are produced by many cells and have systemic effects on the hypothalamic-pituitary-thyroid axis. Administration of tumor necrosis factor (TNF) or interleukin-6 decreases serum TSH levels in healthy human subjects, and TNF and interleukin-1 (IL-1) decrease TSH levels in animals.[87,88,89] Administration of these cytokines recapitulates the alterations in thyroid hormone and TSH levels seen in acute nonthyroidal illness. In rats, TNF reduces hypothalamic TRH content and pituitary *TSH* gene transcription. IL-1 stimulates type II 5'-deiodinase activity in rat brain, which may decrease TSH secretion by increasing intrapituitary T_3 levels.

KEY POINTS

- Thyroid-stimulating hormone (TSH) secretion is regulated through a simultaneous dual control system of thyrotropin-releasing hormone (TRH) stimulation and somatostatin (SS) inhibition from the hypothalamus. Dopamine also has direct effects on hypothalamic hormone secretion that may indirectly impact TSH secretion. Thyroid hormones directly affect pituitary secretion of TSH by combined effects on TRH release from the hypothalamus and SS levels and SS receptor expression on thyrotrope cells.

THYROSTIMULIN

Thyrostimulin is a second glycoprotein that binds to TSHR and can activate signaling by TSHR.[90] Indeed, thyrostimulin binds to TSHR with higher affinity than TSH. Like TSH, thyrostimulin is a heterodimer comprised of an α- and β-subunit, both of which are distinct from those of TSH. Thyrostimulin has been shown to affect several tissues in animal models.[91] However, no effect of thyrostimulin has been shown in humans, and there has not been any report of measurable levels of thyrostimulin in human blood. Thus, the role of thyrostimulin in humans is not known.

THYROID-STIMULATING HORMONE RECEPTOR

TSHR[9,92,93] is a member of the class A subfamily of the ubiquitous family of cell-surface receptors known as GPCRs, or seven transmembrane-spanning domain receptors.[94,95] TSHR is highly conserved across species. In this chapter, TSHR will usually refer to the human receptor.

Protein Structure

Like all GPCRs, TSHR is comprised of an extracellular portion (or ectodomain) and a transmembrane domain comprised of seven alpha-helices, connected by extra- and intracellular loops, respectively (Fig. 65.2). TSHR is most homologous to the receptors for the two other GPHs (receptors for LH/CG and FSH), where the highest homology is within the transmembrane domains.[92]

Another feature that is shared by the GPH receptors is the presence of a large ectodomain to which their cognate ligands bind. The binding sites of TSH (and TSHR-stimulating antibodies found in patient with Graves disease), like binding of GPHs to their cognate receptors, are primarily, if not exclusively, to the extracellular part of TSHR (Fig. 65.2). But in contrast to FSHR and LH/CGR, as well as other GPCRs, which are present on the surface of cells as single polypeptide chains, TSHR may be cleaved within its ectodomain when translocated from the endoplasmic reticulum to the cell surface to generate a receptor composed of two subunits, A/α and B/β, that are held together by disulfide bridges.[96] Thereby, the cleaved sequence of approximately 50 amino acid residues (C-peptide) is excised and lost (Fig. 65.3). It is likely that TSHR is present on the cell surface in both cleaved and uncleaved forms. The biological role of receptor cleavage is still controversial.

Also, like many GPCRs,[97,98] TSHRs may be present on the cell surface as monomers and homodimers.[99,100] The presence of homodimers appears to be important in allowing TSHR to initiate signaling via multiple transduction pathways (see later).

Intracellular Primary and Secondary Signal Transduction Mechanisms

TSH and thyrostimulin (and TSHR-stimulating antibodies found in Graves disease patients; see Chapter 71) activate TSHR by binding primarily, if not exclusively, to its large extracellular N-terminal part. Initiation of TSHR signaling involves coupling to and activation of members of all four G-protein families (G_s, $G_{q/11}$, $G_{i/o}$, $G_{12/13}$)[101] and β-arrestin 1.[102,103] The best-characterized signaling cascades initiated by TSHR are activation of G_s and G_q. G_s activates adenylyl cyclase to increase production of the second messenger cAMP, which in turn activates proteinase kinase A. G_q activates phospholipase C to generate inositol 1,4,5-trisphosphate, which increases intracellular calcium that in turn activates calcium/calmodulin-dependent protein, and 1,2-diacylglycerol, which activates protein kinase C. Activation of $G_{i/o}$ leads to inhibition of cAMP production and activation of $G_{12/13}$ leads to activation of a series of signaling protein kinases. β-arrestin 1–mediated signaling leads to activation of multiple protein kinases like ERK1/2, AKT1, and p38α.[102] Downstream of these initial activations/inhibitions, multiple protein kinase cascades mediate the responses at every level of cellular function. For example, animal cell studies have

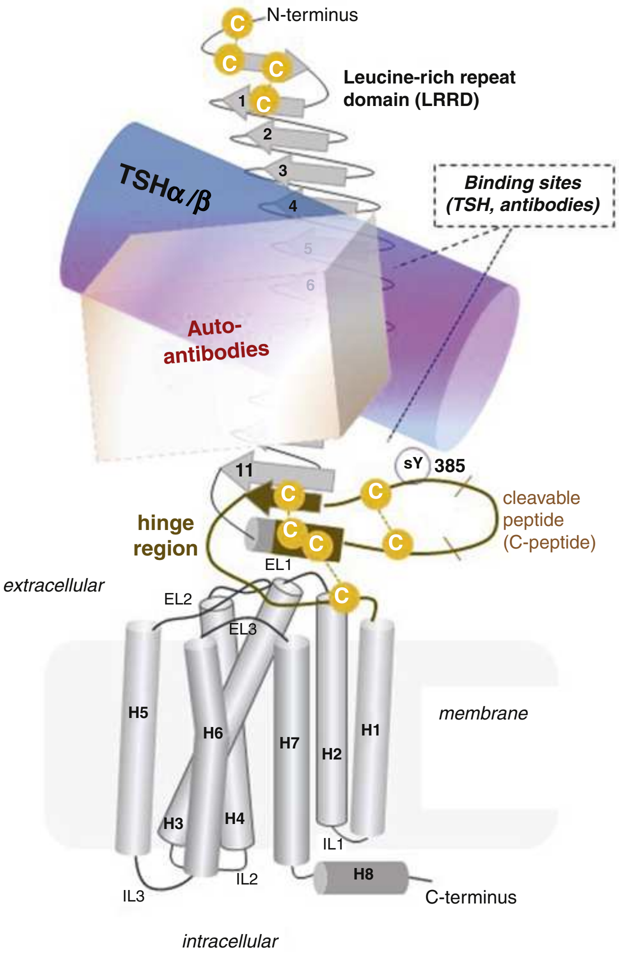

Fig. 65.3 Structural scheme of thyroid-stimulating hormone (TSH) and autoantibodies bound to the TSH receptor (TSHR). The TSHR exposes an extracellular N-terminus of approximately 400 amino acids. TSH interacts with two binding sites, first in the concave site of the leucine-rich repeat domain (LRRD) constituted by 11 leucine-rich repeats, and secondly in the hinge region, e.g., at a sulfated tyrosine (sY385). The TSH-induced signal is conveyed via structural rearrangements between specific interacting components of the hinge region, the LRRD and extracellular loops (ELs), which are termed in their entirety "intramolecular agonist." The extracellular part is characterized by several disulfide bridges participating in the stabilization of the receptor fold. Pathogenic autoantibodies also bind to the extracellular domain of the TSHR and cause Graves hyperthyroidism and thyroid eye disease by persistent, unregulated stimulation of the TSHR. The transmembrane spanning region is constituted by seven helices (H1–7), connected by ELs and intracelluar loops (ILs). The eighth helix is located parallel to the membrane and anchors the receptor to the membrane. The α-subunit of the heterotrimeric G protein binds between the intracellular loops and adjacent transitions to the helices after agonist interaction with the receptor or under basally/constitutively active conditions.

led to the conclusion that increased intracellular cAMP is involved in iodide uptake, thyroid hormone secretion, and cell proliferation. Phospholipase C–dependent pathways are required for iodine organification and thyroid hormone secretion. In addition, the $G_{q/11}$ pathway seems to have an essential role in the adaptive growth of the thyroid gland. It deserves reemphasis that most of the data and conclusions drawn regarding the molecular mechanisms of TSHR signal transduction come from studies of animal cells and engineered model cell systems in culture. Nevertheless, the many steps in the signal transduction pathways that mediate the entirety of TSHR signaling leading to the multiple biologic responses have not been completely elucidated. Moreover, although these studies have provided important information, it has become clear from studies of human thyrocytes in primary culture[104] that the details of the mechanisms elucidated in animal cells do not precisely model signal transduction in human cells.

Thyroid-Stimulating Hormone Receptor Homodimerization

A number of GPCRs have been found to exist on the surface of cells as monomers, homodimers, and heterodimers.[97,98] TSHR is capable of forming homodimers and heterodimers.[99,100] However, to date no physiological function has been found for TSHR heterodimers, which have been shown only in artificial systems. TSHR homodimers, by contrast, have been found in normal human thyrocytes and have effects on signaling.[103] Binding of TSH to TSHR homodimers exhibits the phenomenon of negative cooperativity; that is, after binding of one molecule of TSH to one of the two promoters that comprise the homodimer, binding of a second molecule of TSH to the second protomer exhibits decreased binding affinity.[99] This is a mechanism that allows TSHR to be activated over a large range of TSH concentrations and to signal via different pathways at different TSH doses. For example, low of doses of TSH allow only a single TSH molecule to bind to a monomer or to a homodimer to activate G_s, whereas high doses of TSH allow two molecules of TSH to bind to a homodimer to activate $G_{q/11}$ or Gi/o.[105-108] Laurent et al. were the first to demonstrate that increasing doses of TSH generated a biphasic dose response for cAMP production in normal human thyroid tissue slices *in vitro*. In the cAMP signaling system, coupling to G_s at low TSH doses and to $G_{i/o}$ at high TSH doses leads to a biphasic response of cAMP production to TSH. This biphasic stimulation of cAMP production at low TSH doses and partial inhibition of stimulated production at high TSH doses[107] has been termed an inverted U-shaped dose response curve (IUDRC) (Fig. 65.4). This contrasts the monophasic dose response curve usually reported in cell systems stimulated by TSH, in which increasing doses of TSH lead to progressively increased cAMP production that plateaus at high TSH doses. It is now appreciated that a wide variety of receptor activators may generate IUDRCs.[109,110] IUDRCs have been shown to be exhibited by several other GPCRs[111,112] and in a wide range of pharmaceutical products and approved drug responses.[113] For TSH, the alternative cell-autonomous mechanism of an IUDRC in the cAMP signaling pathway may represent a mechanism to prevent overstimulation of cAMP-mediated responses in thyrocytes.

KEY POINTS

- The thyroid-stimulating hormone receptor (TSHR) is a G protein–coupled receptor with a large extracellular domain to which thyroid-stimulating hormone (TSH), thyrostimulin, and pathogenic TSHR antibodies bind. TSHR can activate members of all four G-protein families and β-arrestin 1, depending on the cell context. Homodimerization of TSHR plays a pivotal role in signaling, including the cell-autonomous biphasic response to TSH for cyclic adenosine monophsphate production.

THYROIDAL ACTIONS OF THYROID-STIMULATING HORMONE

Regulation of Thyroid-Specific Gene Expression

Much of the information regarding regulation of transcription of thyroid-specific genes was initially generated in studies of thyroid development in mice.[114] Although there have been studies of

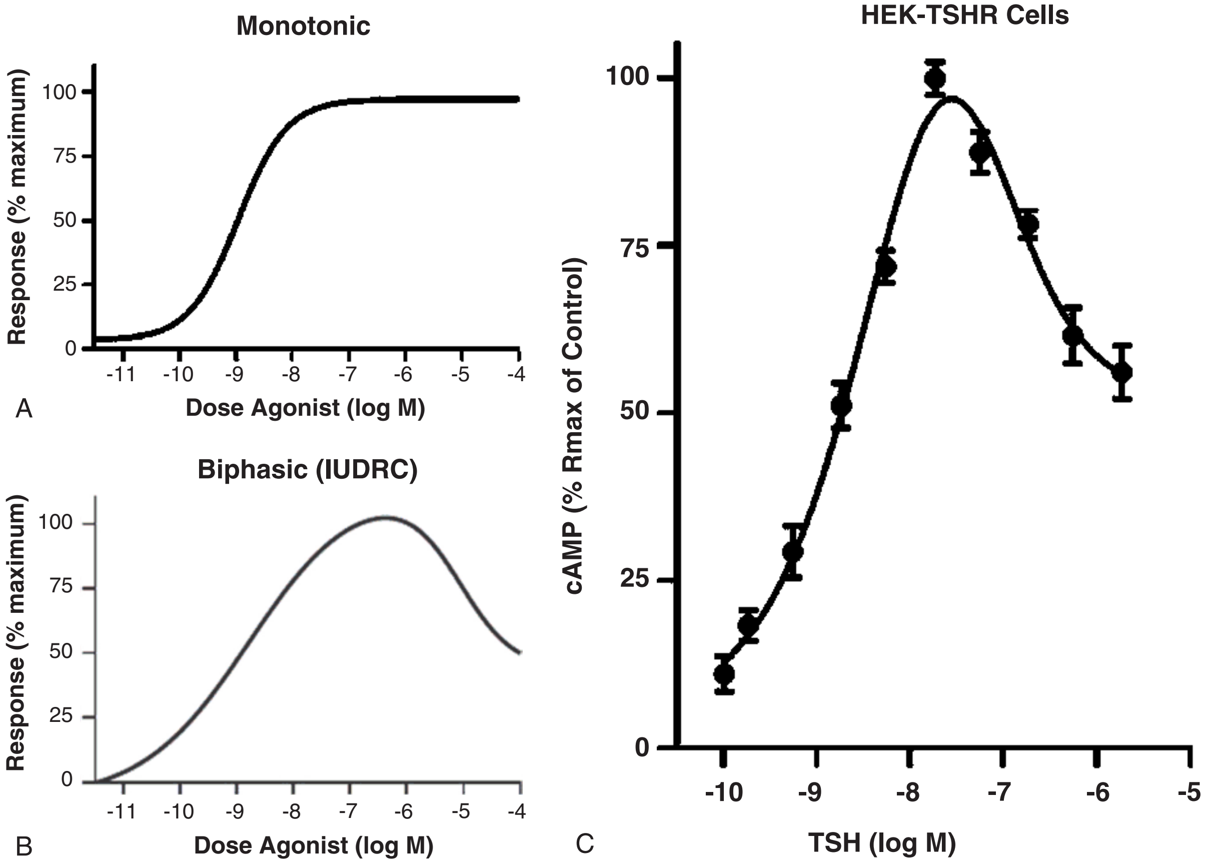

Fig. 65.4 **Biphasic regulation of thyroid-stimulating hormone (TSH)-mediated cyclic adenosine monophosphate (cAMP) production. A,** Typical monotonic dose response curve. **B,** Biphasic (inverted U-shaped dose response curve, IUDRC). **C,** Biphasic regulation of cAMP production by TSH in HEK cells expressing TSH receptors (HEK-TSHR cells). (Adapted from Neumann S, Malik SS, Marcus-Samuels B, et al. Thyrotropin causes dose-dependent biphasic regulation of cAMP production mediated by G_s and $G_{i/o}$ proteins. *Mol Pharmacol.* 2020;97:2–8.)

regulation by TSH in rodent thyroid cell lines and other animal cells in culture, only those findings confirmed in (*in vivo*) rodent studies and in human thyrocytes in short-term primary cell cultures will be emphasized here. This approach was selected, as there have been contradictory and variable findings in those other systems. For this chapter, the thyroid-specific genes whose regulation will be described include thyroglobulin (*TG*), thyroperoxidase (*TPO*), sodium-iodide symporter (*NIS*), deiodinase type 2 (*DIO2*) and *TSHR*. These were chosen because they are regulated by TSH in thyrocytes and are important in thyroid hormone biosynthesis in the thyroid gland, even though several of these genes are expressed in other tissues as well. Although the individual transcription factors that regulate thyrocyte function may be found in other tissues, their expression together appears to occur only in thyroid cells. It is known that four thyroid transcription factors (TTFs) must be expressed simultaneously to allow for the differentiation of stem/precursor cells to thyrocytes during mouse development.[114] These are homeobox protein NKX2-1 (also known as TTF-1), forkhead box protein FOXE1 (also known as TTF-2), paired box protein PAX8, and hematopoietically expressed homeobox protein HHEX. In contrast to the well-described roles of these TTFs in mouse development, their roles and targets in adult differentiated thyroid cells are less well understood. There have been several reports of the effects of deleting individual TTFs on expression of genes in rodent thyroid cell lines, for example, rat FRTL-5 and PCCL3 cells but few in human cell lines.[114-117] For example,[115] showed that *NIS* transcription is upregulated by TSH in normal thyroid cells in culture, and that NKX2-1 overexpression increased *TG* but not *NIS* or *TSHR* in human cells.[116] However, the effects of all four TTFs in TSH-induced regulation of thyroid-specific genes was not delineated. Recently, it was found[117] that NKX2-1, FOXE1, and PAX8, but not HHEX, are required for maximal TSH-induced upregulation of the transcription of the thyroid-specific genes in adult differentiated human thyrocytes. In human thyrocytes in primary culture, individual knockdown of NKX2-1, FOXE1, or PAX8 expression decreased the expression of the mRNAs for *TG*, *TPO*, *DIO2*, *NIS*, and *TSHR*. Knockdown of HHEX had no effect on upregulation of these genes by TSH, but it was found that knockdown of HHEX increased *TG* mRNA in the absence of TSH, and therefore HHEX appears to be a repressor of basal *TG* transcription.[117,118] Thus, it is clear that NKX2-1, FOXE1, and PAX8 are required for optimal expression of thyroid-specific genes induced by TSH, but the role of HHEX on gene transcription in the adult thyroid remains undetermined.[114]

It has recently been revealed that TSH regulation of transcription of genes involved in thyroid hormone biosynthesis in human thyrocytes elicits IUDRCs.[119] The three TTFs—NKX2-1, FOXE1, and PAX8—are required for optimal upregulation of the transcription of *TG*, *TPO*, and *NIS* in rat cell lines.[120] The role of HHEX is least well understood, but it has been reported that it is a repressor of the *TG* promoter and that it is able to abolish the activating effects of PAX8 and NKX2-1 in engineered cells.[119] In primary cultures of human thyrocytes,[120] TSH elicited a biphasic response in terms of stimulation of transcription of *TG, TPO, DIO2, NIS,* and *TSHR*. Stimulation by TSH of transcription of these five genes was dependent on NKX2-1, FOXE1, and PAX8, as knocking down each of these TTFs inhibited upregulation of *TG, TPO, DIO2, NIS*, and *TSHR*.[119] In human thyrocytes, HHEX does not appear to be involved in upregulation of thyroid specific genes but does appear to repress basal levels of TG. However, as noted above, the full signaling pathways participating in these regulations have not been elucidated, but it is clear that multiple pathways are involved in the transcriptional regulation of each of these genes. Thus, it has been proposed that cell-autonomous, biphasic regulation of thyroidal responses to TSH complements the well-known feedback inhibition by thyroid hormones on TSH secretion from the pituitary gland to prevent hyperstimulation of thyroid gland function.

KEY POINTS

- A cell-autonomous, biphasic regulation of thyroid-stimulating hormone (TSH) receptor–mediated thyroid-specific gene expression by different doses of TSH has been shown in normal human thyroid cells in primary cultures. This biphasic response to TSH may be another fine-tuning regulatory mechanism, in addition to the hypothalamic-pituitary-thyroid axis negative feedback and inhibition by thyroglobulin, to limit hyperstimulation of thyroid gland function.

THYROID-STIMULATING HORMONE RECEPTOR/INSULIN-LIKE GROWTH FACTOR 1 RECEPTOR CROSSTALK

Crosstalk between cell-surface GPCRs and receptor tyrosine kinases (RTKs) is a ubiquitous phenomenon that leads to broadening of the signaling responses initiated by the specific activation of one receptor.[94] In the case of GPCRs and RTKs, crosstalk may occur after activation of either receptor; this has been termed bidirectional transactivation.[121,122] Although these interactions may occur at several steps in the signal transduction pathways, a large number of these involve GPCR–RTK interactions at the cell surface membrane. Crosstalk of this type may be dependent on the generation of a ligand for the second receptor by activation of the first receptor, or may be independent of ligand generation.[123] Crosstalk independent of ligand generation may result from receptor–receptor interactions: when the binding of a ligand to one receptor causes, via direct interactions, a change in the ligand recognition, decoding, and trafficking processes of another receptor.[124] However, an alternative to direct receptor–receptor interaction may be the formation of a multiprotein complex ("signalosome") in which two receptors are brought in close proximity and may influence each other's signaling. This type of receptor–receptor interaction appears to be the mechanism of crosstalk between the TSHR, a GPCR, and the insulin-like growth factor 1 receptor (IGF1R), an RTK (Fig. 65.5). Functional interactions between TSHR and IGF1R in thyrocytes *in vitro*[125-128] have been reported for many years; however, the majority of these studies were performed in rodent cell lines. Functional interactions between TSHR and IGF1R have also been shown *in vitro* in orbital fibroblasts from patients with Graves disease.[129-132] Studies in primary cultures have recently confirmed TSHR/IGF1R crosstalk in normal, differentiated, human thyrocytes[133] (Fig. 65.5). Crosstalk was shown in two ways. First, simultaneous stimulation by TSH and IGF1 led to a synergistic increase in the upregulation of *NIS* gene transcription and NIS protein expression. And second, an IGF1R kinase inhibitor inhibited stimulation by TSH.[133] These findings were confirmed and expanded by showing that β-arrestin 1 anchors TSHR and IGF1R in a signalosome, and that disruption of the signalosome by knocking down β-arrestin 1 inhibits TSHR/IGF1R crosstalk and the synergistic increase in NIS expression.[134] Thus, TSHR/IGF1R crosstalk has an important role in regulation of thyrocyte function under physiological stimulation by TSH, but also in pathophysiological stimulation by TSHR-stimulating antibodies, especially in TED (see Chapter 72).

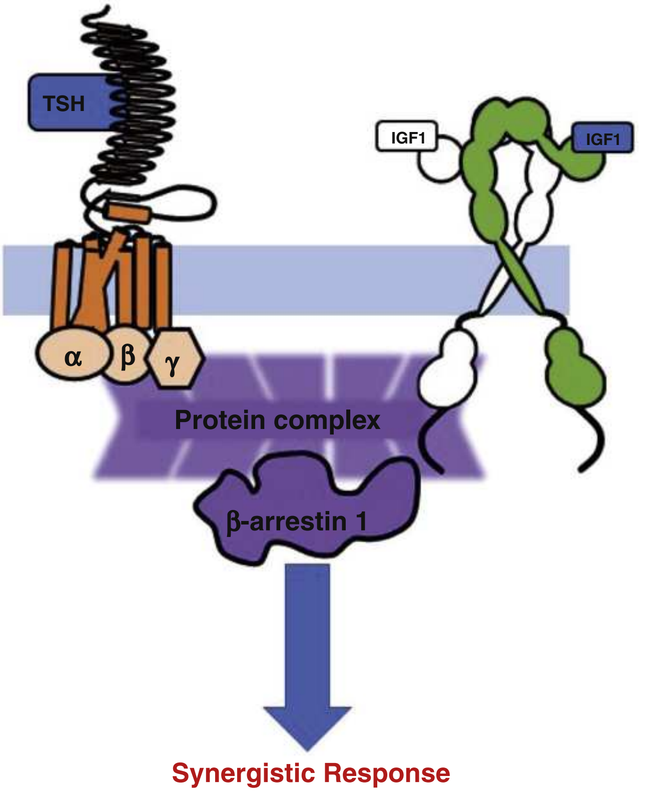

Fig. 65.5 Model of thyroid-stimulating hormone receptor (TSHR)/insulin-like growth factor receptor 1 (IGF1R) crosstalk. Activation of TSHR by thyroid-stimulating hormone (TSH) activates two signal transduction pathways—one that is independent of the IGF1R and another that is dependent on IGF1R. TSHR and IGF1R are in close proximity within a signalosome for which β-arrestin 1 acts as a scaffold. TSHR- and IGF1R-mediated pathways combine, leading to a more synergistic stimulation of *NIS* gene and protein expression in primary cultures of human thyrocytes. TSHR/IGF1R crosstalk leads also to a synergistic increase in hyaluronan secretion in Graves orbital fibroblasts, which is a major component of thyroid eye disease (see Chapter 72). (Modified from Krieger CC, Place RF, Bevilacqua C, et al. TSH/IGF-1 receptor cross talk in Graves' ophthalmopathy pathogenesis. *J Clin Endocrinol Metab*. 2016;101:2340–2347 and Krieger CC, Neumann S, Gershengorn MC. TSH/IGF1 receptor crosstalk: Mechanism and clinical implications. *Pharmacol Ther*. 2020;209:107502.)

KEY POINTS

- TSHR/IGF1R crosstalk initiated by TSHR activation has been observed in cell culture in thyrocytes and Graves orbital fibroblasts, and it has been demonstrated that it plays a pivotal role in the pathophysiology of Graves hyperthyroidism and TED. The activated TSHR engages the IGF1R in a signalosome that is scaffolded by β-arrestin 1, and this crosstalk induces a synergistic increase in NIS expression in thyrocytes and hyaluronan secretion in Graves orbital fibroblasts.

Regulation of Thyroid Hormone Synthesis

Thyroid hormone synthesis requires iodide uptake, TG biosynthesis, oxidation of iodide, and coupling of two iodotyrosines into iodothyronines within TG.[135] Iodide is actively transported into the thyrocyte by NIS within the thyrocyte basal membrane and diffuses down an electrical gradient to the apical membrane. As mentioned above, TSH stimulates expression of TG and NIS by increasing the rates of their transcription. In some species, TSH also has been reported to increase iodide uptake by increasing thyroid blood flow. Iodide oxidation and coupling to tyrosine residues within TG, and iodotyrosine coupling to iodothyronines are catalyzed by the same enzyme, TPO, which is within the apical membrane of the thyrocyte. Hydrogen peroxide is generated by two apical membrane dual oxidases. TSH stimulates the rate of transcription of TPO and of dual oxidase 2 (DUOX2), which is the major dual oxidase in the thyrocyte. In human thyrocytes, hydrogen peroxide, which oxidizes iodide for coupling, but not TPO, is also stimulated by direct activation of preformed DUOX2 TSH.[136]

Regulation of Thyroid Hormone Secretion

Secretion of thyroid hormones requires endocytosis of follicle TG via the apical membrane, its hydrolysis within the cell, and release of thyroid hormones from the basolateral membrane of the cell. The major endocytotic pathway involves pseudopod extrusion from the apical surface of the thyrocyte and engulfment of particles of TG. This phenomenon is mediated by direct activation of intracellular signaling pathways stimulated by TSH (for review, see[137]). The endocytosed vesicles then fuse with lysosomes in which TG is hydrolyzed. Thyroxine is the major iodothyronine in TG. In this process, a small amount of T_4 is deiodinated by 5-deiodinases to T_3, thereby increasing the amount of T_3 that is secreted. Free thyroid hormones are released by the thyroid hormone transporter SLC16A2. It has also been suggested that thyroid hormones may be released by transcytosis around the lateral sides of the thyrocyte. TG is also released by the thyroid gland. Like thyroid hormones, TG secretion appears to be via endocytosis, but transcytosis has been proposed also.

EXTRATHYROIDAL ACTIONS MEDIATED BY THYROID-STIMULATING HORMONE RECEPTOR

TSHR has been shown to be expressed in a number of extrathyroidal tissues, including fat cells,[138] fibroblasts, preadipocytes, and adipocytes in the retroorbital space,[131,139] osteoblasts and osteoclasts,[140] lymphocytes,[141] erythrocytes,[142] brain,[143] and pituitary.[144] Expression of TSHR has often been demonstrated at the level of mRNA and in fewer tissues at the level of functional TSHR. Nevertheless, the physiologic role(s) of TSHR in most of these tissues is not well-defined. However, evidence has been reported for a pathophysiological role of TSHR in the orbital space (see Chapter 72).

Functional TSHRs are expressed in adipocytes,[139] and TSH was shown to stimulate proliferation and inhibit differentiation of rat preadipocytes *in vitro*.[145] Recently, a study using adipose tissue–specific partial knockdown in mice[146] reported that loss of TSHRs in white and brown adipose tissue led to a predisposition to weight gain and effects on regulation of glucose tolerance, lipid metabolism, adipokine profile, and thermogenesis. Nevertheless, at this time, the physiologic role of the TSHR in adipose tissue has not been well-defined.

There is abundant evidence of an important role of thyroid hormones on bone metabolism.[147] By contrast, although TSHRs have been found in bone, the question of whether there is a direct, thyroid hormone–independent action of TSH on bone remains unresolved.[140,148] When TSHR is overexpressed in a human preosteoblast cell line,[102,105,149] several responses to TSH have been described. These include: 1) TSHR couples to several different G proteins to induce upregulation of genes associated with osteoblast activity—interleukin 1, osteopontin, and alkaline phosphatase; 2) TSH can stimulate β-arrestin 1–mediated signal transduction, and β-arrestin 1 in part mediates TSH-induced preosteoblast differentiation; and 3) TSHR/IGF1R crosstalk synergistically increased osteopontin secretion by TSH and IGF1.

TSHR expression has been demonstrated in rodent osteoblasts and osteoclasts. Direct effects of TSH were described in bone,[150] where it modulates TNF alpha and receptor activator of nuclear factor-κB ligand production to decrease osteoclast differentiation.[151] TSHR knockout causes osteoporosis and focal osteosclerosis in mice.[152] TSH administration inhibits bone loss in adult, ovariectomized rodents, consistent with the idea that TSH is an activator of bone formation.[153] Overall, *in vivo* studies in mice and rats propose TSH as a fine-tuning regulator of bone homeostasis, and these findings have been comprehensibly reviewed.[140,147,154,155]

Several clinical studies have also pointed to direct action of TSH on bone. Administration of recombinant human TSH (rhTSH) in postmenopausal women increased serum N-terminal propeptide of type-I procollagen, a marker of bone formation, demonstrating an anabolic effect of TSH in humans.[156] Mazziotti et al. showed that short–term rhTSH stimulation leads to a reversible inhibition of bone resorption in postmenopausal women, suggesting a role for TSH in patients with bone loss and a high bone turnover rate.[157] Furthermore, epidemiological studies demonstrated a tight relationship between low TSH levels and parameters of bone loss and fracture risk. However, the role of TSH on the adult skeleton and its mechanisms of action in human bone have yet to be definitively demonstrated and are still controversial (reviewed in[140,155,158]).

Also, although TSHR is expressed in human bone, TSH is not expressed in primary human osteoblasts or osteoclasts.[91] Pituitary TSH works systemically, and therefore it is likely that it can activate TSHRs in bone. Thyrostimulin has been considered as a regulator of bone formation, perhaps acting in an autocrine/paracrine fashion. In contrast to TSH, thyrostimulin is expressed in osteoblasts and osteoclasts.[150] The combination of *in vivo* and *in vitro* studies demonstrated a role for thyrostimulin during skeletal development, but an essential role in the adult skeleton has not been shown.[150]

The presence of TSHRs in orbital fibroblasts, preadipocytes, and adipocytes in the retroorbital tissue led to speculation about their possible pathophysiological role in TED (see Chapter 72). The hypothesis generated was that the thyroid-stimulating antibodies (or TSHR-stimulating antibodies [TSHRSAbs]), the well-recognized mediators of Graves hyperthyroidism, were a major component of TED by activating TSHRs on resident retroorbital cells.[131,16] It has been suggested that a second source of these target cells may be circulating, bone marrow–derived cells termed fibrocytes.[159] Furthermore, it has been proposed that the pathogenesis of TED involves IGF1R also[160,161] (see the earlier section on Thyroid-Stimulating Hormone Receptor /Insulin-like Growth Factor 1 Receptor Crosstalk). It is important to note that these hypotheses are supported primarily by studies in primary cultures of cells obtained at surgical decompression from retroorbital tissue termed Graves orbital fibroblasts or fibrocytes, and not from studies in intact humans. An interesting controversy regarding the pathogenesis of TED has arisen as to whether activation of the IGF1R is because it is a direct target of stimulating antibodies or whether IGF1R is activated secondarily after activation of TSHRs by TSHRSAbs via TSHR/IGF1R crosstalk. We favor the hypothesis that TED pathogenesis involves TSHR/IGF1R crosstalk. (A more complete discussion of the pathogenesis of TED can be found in Chapter 72.)

KEY POINTS

- Extrathyroidal thyroid-stimulating hormone receptor (TSHR) expression has been reported in orbital fibroblasts, bone, brain, kidney, testis, heart, and adipose tissue. Thyroid-stimulating hormone (TSH) is a fine-tuning regulator of bone homeostasis. However, despite evidence of an important role of thyroid hormones on bone metabolism, the question of whether there is a direct, thyroid hormone-independent action of TSH on bone remains unresolved. In contrast, TSHR in orbital fibroblasts has been shown to play a pivotal role in the pathogenesis of thyroid eye disease. TSHR-induced signaling is mediated through an insulin-like growth factor 1 receptor (IGF1R)-independent pathway and an IGF1R-dependent pathway.

THYROID HORMONE TRANSPORT AND METABOLISM

The key determinants of intracellular thyroid hormone bioavailability are (1) thyroid hormone transporter proteins at the plasma membrane and (2) thyroid hormone deiodinating enzymes (deiodinases [DIOs]) with their catalytic sites located intracellularly.[1,2] Together, thyroid hormone transporters and DIOs govern intracellular concentrations of the bioactive hormone 3,5,3'-tri-iodothyronine (T3). As such, the genomic actions of T3 are exerted through binding to the nuclear T3 receptor, which functions as a ligand-dependent transcription factor.[3]

The majority of the thyroid hormone transporters that have been identified accept a broad range of substrates, with only a few transporters exhibiting high specificity towards iodothyronines.[1] Table 66.1 displays the main characteristics of human thyroid hormone transporters. The monocarboxylate transporter 8 (MCT8; solute carrier family 16A2 [SLC16A2]) transports 3,5,3',5'-tetra-iodothyronine (thyroxine [T4]), T3 as well as 3,5',3'-tri-iodothyronine T3 (reverse T3 [rT3]) and 3,3'-di-iodothyronine (3,3'-T2).[4] MCT8 is expressed in different tissues, including the developing and adult brain (endothelial cells of the blood-brain barrier [BBB], neuronal cells, choroid plexus), thyroid, liver, kidney, and pituitary. MCT8 is physiologically relevant, as evidenced by the severe clinical sequelae in patients with defective MCT8 (see later section on MCT8 Deficiency). The highly homologous MCT10 (SLC16A10) preferentially transports T3 over T4, but also facilitates transport of aromatic amino acids.[5] MCT10 has a broad tissue expression, including skeletal muscle, kidney, heart, and placenta. The organic anion transporting polypeptide 1C1 (OATP1C1) is also regarded as a T4 transporter.[6] Interestingly, there is a notable species-specific difference in expression: murine *Oatp1c1* is expressed at the BBB, and as such is redundant with Mct8 function; in contrast, human *OATP1C1* is highly expressed in astrocytes, but not in endothelial cells of the BBB. The transmembrane transporter SLC17A4 transfers T3 and T4 as effectively as MCT8[7] and, given its expression along the gastrointestinal tract, one may anticipate that it is involved in intestinal transport of thyroid hormone. While MCT8 and OATP1C1 are essential for thyroid hormone regulation in the brain, the physiological relevance of MCT10 and SLC17A4 is unknown.

There are different pathways of thyroid hormone metabolism (Fig. 66.1), of which deiodination is the most prominent.[2] Therefore, the bioactivity of thyroid hormone is importantly dictated by the three DIOs that facilitate outer-ring deiodination (activation) or inner-ring deiodination (inactivation) of iodothyronines. These DIOs are small (30-kDa) membrane-bound enzymes that function as homodimers, with two distinct domains: an N-terminal transmembrane domain (TMD) and a C-terminal globular cytosolic catalytic domain. The molecular structure of cytosolic DIO3 domain has been solved[26] and shows a thioredoxin-like fold with a selenocysteine-containing active center. The three DIOs are highly homologous, but differ in biochemical characteristics, expression patterns, and regulation (Table 66.2).

DIO1 possesses both outer-ring and inner-ring deiodination activity, although it is mostly effective in degrading rT3. It is present in the plasma membrane and highly expressed in liver, kidneys, and thyroid,[2] with both hepatic and renal DIO1 activity positively regulated by systemic serum thyroid hormone concentration. DIO1 is involved in the clearance of rT3 from the circulation and contributes to the production of T3 from T4 present in the circulation. Sulfated T4 and T3S are rapidly degraded by DIO1, possibly serving as a mechanism to retrieve iodide before the T3 or T4 molecules are removed from the body.

DIO2 catalyzes conversion of T4 to T3 and of rT3 to 3,3'-T2 and is expressed in the brain, pituitary, brown adipose tissue, and skeletal muscle. Together with DIO1, DIO2 is responsible for the production of serum T3 from T4, with DIO2 having the larger contribution.[2] In addition, DIO2 facilitates tissue-specific conversion of T4 to T3 independent of systemic thyroid hormone concentrations. This role of DIO2 allows dynamic control of intracellular hormone availability at different developmental stages and under different conditions.[2]

DIO3 degrades T3 to 3,3'-T2 and T4 to rT3, thereby preventing T4 from being activated. DIO3 is highly expressed in fetal tissues, in uterus and placenta; in adult life, expression is mainly limited to the brain, skin, and β cells of the pancreas. DIO3 can be reactivated under specific pathological conditions, such as severe illness and fasting, with impact on systemic thyroid hormone homeostasis. Cell-specific reactivation in certain conditions, such as myocardial infarction, tissue regeneration, or hypoxia, can alter cell-specific thyroid hormone signaling independent of systemic thyroid hormone concentrations.[2]

Despite considerable differences in thyroid hormone economy between animals and humans, mice defective in one or more DIOs

TABLE 66.1 **Characteristics of Human Thyroid Hormone Transporters**

Transporter	Gene Name	Aliases[1]	Tissue/Cells and Subcellular Localization	Substrate (Km in µM) Uptake	Substrate Efflux	Other Substrates (Km)	Inhibitor
OATP1A2	*SLCO1A2*	OATP-A, OATP, OATP1	Brain, endothelial cells of BBB, kidney (AM of distal nephron), liver (cholangiocytes), lung, ciliary body, placenta (syncytiotrophoblasts)	T3 (~6.5) > T4 (~8.0), rT3; T3S > T4S; rT3S	n.d.	Tauroursodeoxycholate (~19 µM), DHEAS (~7 µM), cholate (~93 µM), taurocholate (~60 µM), cholate (~93 µM), BSP (~20 µM), E3S (~16-59 µM), ouabain, N-methyl quinine, PGE2, glycocholate	BSP, rifampicin, flavanones, polymethoxyflavanones
OATP1B1	*SLCO1B1*	OATP-C, LST-1, OAPT2, OATP6	Liver (BLM of hepatocytes)	T4S, T3S, rT3S > rT3 >T4 (~3.0), T3 (~2.7)	n.d.	BSP (~0.3 µM), cholate (~11 µM), taurocholate (~10-34 µM), glycocholate, E3S (various), DHEAS (~22 µM), PGE2, E217βG (~8.2 µM)	BSP, flavanones, polymethoxyflavanones
OATP1B3	*SLCO1B3*	OATP8, LST-2	Liver (BLM of hepatocytes, central vein>portal vein)	T3 (~6.4) > T4	n.d.	Bilirubin (~39 nM), BSP (~0.4 µM), cholate (~42 µM), taurocholate (~6-42 µM), glycocholate (~43 µM), E3S (~73 µM), methotrexate (~25 µM), DHEAS, ouabain, digoxin, E217βG, PGE2	BSP
OATP1C1	*SLCO1C1*	OATP-F, OATP-RP5 (human), BSAT1 (rat), Oatp2 (mouse), Oatp14	Brain (glial and neuronal (precursor) cells), BBB, choroid plexus, testis (Leydig cells), ciliary body, adipose tissue	T4 (~0.09-0.12) >T4S (~3) > rT3 (~0.13) > T3	n.d.	E3S, BSP, E217βG, taurocholate	BSP
OATP2B1	*SLCO2B1*	OATP-B, OATP-RP2 (human), moat1 (rat), Oatp9	Ubiquitously (including hepatocytes (BLM) syncytiotrophoblasts (BLM), enterocytes (AM, BLM), BBB (AM)	[T4 (~0.31-0.77)]	n.d.	BSP (~0.7 µM), E3S (~6.3 µM), DHEAS	BSP, flavanones, polymethoxyflavanones
OATP3A1 (two protein isoforms: V1 and V2)	*SLCO3A1*	OATP-D, OATP-RP3 (human), Pgt2 (rat), MJAM (mouse), Oatp11	Brain (white/grey matter, choroid plexus), testes, ciliary body, heart, ovary	T4	n.d.	E3S, PGE2 (~0.22-0.37 µM), vasopressin	
OATP4A1	*SLCO4A1*	OATP-E, OATP-RP1 (human), oatpE (rat), Oatp12	Ubiquitous (except gastrointestinal tract and brain)	T3 (~0.9)> rT3>T4	n.d.	Taurocholate (~14.9 µM), PGE2	BSP
OATP4C1	*SLCO4C1*	OATP-H	Kidney	T4, T3 (~0.9)	T3: no T4: n.d.	Digoxin, ouabain, methotrexate

TABLE 66.1 Characteristics of Human Thyroid Hormone Transporters—cont'd.

Transporter	Gene Name	Aliases[1]	Tissue/Cells and Subcellular Localization	Substrate (Km in μM) Uptake	Substrate Efflux	Other Substrates (Km)	Inhibitor
NTCP	*SLC10A1*		Liver (basolateral membrane of hepatocytes)	T4S, T3S > T4, T3	No	Eprotirome, cholate, taurocholate (~6-34 μM), glycocholate (~27 μM), chenodeoxycholate-3-sulfate, E3S (~27-60 μM), DHEAS, BSP (~3.7 μM)	Myrcludex B, BSP, furosemide
SLC17A4	*SLC17A4*	NPT homolog	Gastrointestinal tract, liver, pancreas, kidney	T3, T4	n.d.	p-[glycyl-2-3H]p-aminohippuric acid (PAH), (uric acid)	n.d.
LAT1	*SLC7A5*		Brain, placenta, testis, leukocytes, fetal liver, bone marrow	3,3′-T2 > rT3 > T3 > T4; MIT (~13)	3,3′-T2	Broad spectrum of (neutral) amino acids (excluding Gly, Ala, Ser) (~12-120 μM), L-dopa (~34 μM), pregabalin (~288 μM), IMT (22.6 μM)	BCH, JPH203
LAT2	*SLC7A8*		Kidney, placenta, brain, spleen, prostate, testis, ovary	3,3′-T2 > T3; MIT	None	Broad spectrum of (neutral) amino acids (including Gly, Ala, Ser) (~35–200 μM)	BCH, NEM
LAT3	*SLC43A1*		Placenta, liver, kidney, pancreas, skeletal muscle, heart	None	3,3′-T2, MIT, (rT3)	Neutral amino acids (Leu, Ile, Val, Phe > Met, Tyr > others) (~8–30 μM)	BCH, NEM
LAT4	*SLC43A2*		Placenta, leukocytes, skeletal muscle, spleen, kidney and heart	None	3,3′-T2, MIT, (rT3)	Neutral amino acids (Ile, Leu, Met, Phe >>> others) (~100–200 μM)	BCH, NEM
MCT8	*SLC16A2*	XPCT, MCT7	Developing and adult brain: vascular endothelial cells of BBB, choroid plexus, liver, kidney, thyroid, pituitary	T3 (~7.5 μM short isoform, ~1 μM long isoform), T4 (~3 μM) > rT3 > 3,3′-T2 > 3,5-T2 >3′,5′-T2	T3, T4	-	Silychristin
MCT10	*SLC16A10*	TAT1	Kidney, skeletal muscle, placenta, heart, developing brain, hypothalamus, choroid plexus	T3 >3,5-T2 >>T4, rT3	T3	Phe, Tyr, Trp (~400–700 μM), L-dopa (~1.2 mM)	Trp

[1] Ambiguous protein names (similar names used for distinct proteins, tissue-specific names) are indicated in bold.

LST, Liver-specific transporter, *OATP*, organ anion transporting polypeptide; *OATP-RP*, organ anion transporting polypeptide–related protein; *BSAT*, brain-specific anion transporter; *E3S*, estrone-3-sulfate; *PGE2*, prostaglandin E2; *E217βG*, 17β-glucuronosyl estradiol; *IMT*, 3-iodo-α-methyl-L-tyrosine; *NEM*, N-ethylmaleimide; *XPTC*, X-Linked PEST-containing transporter; *TAT*, T-type amino acid transporter; *BLM*, basolateral membrane; *AM*, apical membrane; BSP, sulfobromophthalein; BBB, blood-brain barrier; BCH, 2-aminobicyclo-(2,2,1)-heptane-2-carboxylic acid; DHEAS, dehydroepiandrosterone sulfate; MIT, monoiodotyrosine.

If the transport of different iodothyronines has been studied in parallel, the substrates are listed in order of apparent substrate preference with a , (comma sign) denoting equal efficacy, and > denoting greater efficacy. If the transport of iodothyronines has not been studied in parallel, a ; (semicolon sign) is used, and substrates are not ranked in a specific order.

have been helpful to dissect their role.[8] Table 66.2 provides the main features of Dio knockout (KO) mice models. *Dio1* null mice exhibit raised T4 and rT3, with normal T3 and thyroid-stimulating hormone (TSH) concentrations.[9] The *Dio2* null mice has high T4 and TSH but normal T3 concentrations and shows growth retardation and defective auditory function.[10,11] Murine *Dio3* deficiency is associated with partial embryonic and neonatal lethality, and surviving mice show severe growth retardation, impaired fertility, and central hypothyroidism.[12] The phenotypes of the murine *Dio1* and *Dio2* double KO mice are surprisingly mild, with serum T3 level, general health, and reproductive capacity apparently not affected, and brain function only somewhat impaired.[13] However, the serum rT3 is elevated 6-fold in the *Dio1/Dio2* null mouse, while only 2-fold in the *Dio1* knock-out mouse and not at all in the *Dio2* KO mouse. A mouse model with complete DIO deficiency, the triple *Dio1/Dio2/Dio3* KO, has survival and growth issues that occur mainly in the embryonic and neonatal period, and many of the mice are infertile. However, the healthy surviving *Dio1/Dio2/Dio3* mice have normal growth, can be bred, and have little gross neurological phenotype, and serum thyroid hormone concentrations are unremarkable.[8,13]

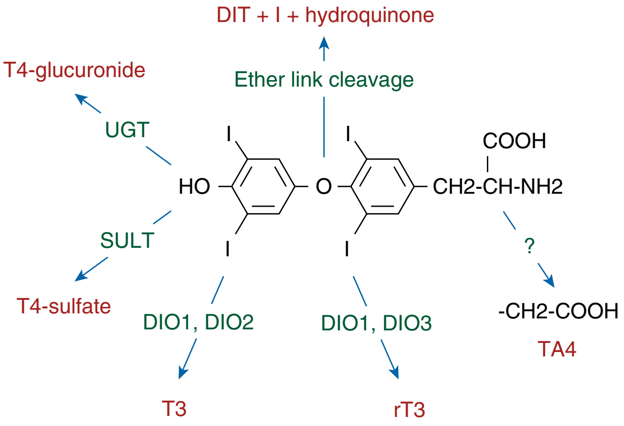

Fig. 66.1 **Pathways of thyroid hormone metabolism.** Deiodination by the three types of deiodinating enzymes (DIO1, DIO2, DIO3) catalyzes removal of iodine moieties. Sulfation and glucuronidation are catalyzed by sulfotransferases (SULTs) and UDP-glucuronosyltransferases (UGTs), respectively. Ether link cleavage and side-chain modification result in alternative products.

The systemic and localized control of thyroid hormone signaling is essential for development, growth, and normal adult life, requiring dynamic regulation to allow for constant adjustment to thyroid hormone signaling according to endogenous and environmental demands. However, the versatility of the system also can lead to the dysregulation of DIO expression, resulting in abnormal systemic or local thyroid hormone concentrations. A striking clinical condition that affects DIO activity is observed in critically ill patients with a substantial drop in circulating T3, at least in part attributed to changed DIO expression and activity in one or more affected tissues.[14,15] Other

TABLE 66.2 Characteristics of Iodothyronine Deiodinases

Characteristics		DIO1	DIO2	DIO3
Function		Plasma T3 production rT3 clearance	Local T3 production	T3 and T4 clearance rT3 production

PTU, Propylthiouracil; *TSH*, thyroid-stimulating hormone.

examples include patients with Graves disease[16] and McCune–Albright syndrome,[17] in which higher serum T3 concentrations correlated with higher thyroidal DIO1 and DIO2 activities. Changes in DIO activity are also reported in several neoplasias, with depletion or excess of thyroid hormone promoting modifications in tumoral growth and development.[2] One of the most striking examples is a severe form of hypothyroidism due to high levels of DIO3 activity in vascular tumors such as hepatic hemangiomas.[18] Depending on tumor size and the levels of *DIO3* expression, the DIO3 activity may inactivate circulating thyroid hormones faster than the thyroid gland can secrete, resulting in a condition known as consumptive hypothyroidism.

The knowledge that DIO activity can affect thyroid hormone concentrations dramatically, influencing patient treatment and potentially outcome, raises the possibility that patients can benefit from genome-wide association studies that identify single nucleotide polymorphisms (SNPs) in *DIO* genes associated with serum thyroid hormone concentrations. These studies show that common variations in *DIO1*, but not *DIO2* or *DIO3*, have a moderate-to-strong relationships with systemic thyroid hormone concentrations.[19,20] With regard to identifying SNPs in *DIO3*, their impact may be affected by genetic imprinting, with *DIO3* being preferentially expressed from the paternal allele.[21] There are several studies describing an association between *DIO2* SNPs and clinical syndromes, including hypothyroidism, hypertension, type 2 diabetes, and mental disorders; however, these associations have not been universally reproduced in all population studies.[2,19] This observation confirms the notion that serum thyroid hormone concentrations and related phenotypes are controlled by a multitude of factors, including genetic background, diet, the interplay between gene networks, and environmental factors. While there is increasing evidence that *DIO2* polymorphisms may play a role in dysregulation of thyroid hormone metabolism, further research should be performed to clarify these associations. Several independent studies suggest that *DIO1* polymorphisms are linked with abnormal thyroid hormone metabolism, and further investigation will determine if this should be taken in consideration for treatment of affected patients.[19]

The human *DIO* genes have been subject investigation for a long time; however, the identification of pathogenic genetic defects has remained elusive. Only recently, two unrelated families were identified to be heterozygous for pathogenic variants in *DIO1*[22] (see later section on Iodothyronine Deiodinase I Deficiency).

All three DIOs have the amino acid selenocysteine (Sec) in their catalytic site, providing enhanced substrate affinity and a fast turnover rate for the deiodination reaction. In humans, more than 25 different Sec-containing proteins, referred to a selenoproteins, have been identified. The Sec residue is encoded by a UGA triplet that in functions as a stop codon in nonselenoproteins. Accordingly, recoding of UGA, enabling incorporation of Sec during selenoprotein synthesis, depends on the presence of a SElenoCysteine Insertion Sequence (SECIS) element, a stem-loop structure in the 3′ untranslated region of the mRNA. The SECIS element attracts a number of cofactors, including SECIS-binding protein 2 (SECISBP2 or SBP2) and Sec-tRNA, the selenocysteine tRNA encoded by *TRU-TCA1-1*. Genetic defects in this pathway, e.g., *SECISBP2, SEPSECS,* and *TRU-TCA1-1*, affects generation of most if not all selenoproteins and, consequently, results in a multisystem disorder. Homozygous and compound heterozygous mutations have been described in *SEPSECS* and are linked with a disorder classified as autosomal recessive pontocerebellar hypoplasia type2D (OMIM 613811), also known as progressive cerebellocerebral atrophy.[27-29] The effect of *SEPSECS* mutations on selenoprotein expression and thyroid hormone metabolism has not been studied in detail and suggests that, in contrast to *SECISBP2* and *TRU-TCA1-1* mutations, selenoprotein deficiency is not generalized; it is unclear if thyroid hormone metabolism is affected, and therefore this will not be discussed any further. However, in patients with *SECISBP2* and *TRU-TCA1-1* mutations, decreased levels of active DIOs mediate abnormal thyroid hormone metabolism, with elevated free T4 (FT4), low or low-normal free T3, raised rT3, and normal or slightly high TSH concentrations.[29]

KEY POINTS

- Cellular thyroid hormone regulation is governed at multiple levels: (1) plasma membrane transporters facilitate influx and efflux of thyroid hormones, (2) intracellular metabolism of thyroid hormone is catalyzed by three deiodinating, selenocysteine-containing enzymes, and (3) genomic actions of thyroid hormone are mediated through binding of 3,5,3′-tri-iodothyronine to its nuclear receptor.

DISORDERS OF THYROID HORMONE TRANSPORT

MCT8 Deficiency

Clinical Phenotype. Disrupted thyroid hormone transport due to mutations in *MCT8* (*SLC16A2*) underlies the severe clinical features of MCT8 deficiency. In 2004, mutations in *MCT8* were linked to patients with an X-linked form of intellectual and motor disability and abnormal thyroid function tests.[30,31] Soon afterwards, it was realized that this disorder had been recognized decades before by Allan, Herndon, and Dudley, and ever since was documented as the Allan–Herndon–Dudley syndrome.[32] Over 200 families have been reported, and the estimated prevalence is approximately 1 in 70,000 males.[33,34] Most children are born after an uneventful pregnancy and delivery. The age of presenting symptoms is approximately 4 months, with developmental delay, hypotonia, poor weight gain, and feeding problems most commonly reported. At examination, most patients have a global hypotonia, with the inability to hold the head upright, as well as upper trunk slipping through. Dystonic posturing of limbs starts in the first year of life. Both dystonia and spasticity contribute to hypertonia and exaggerated deep tendon reflexes. As a consequence, scoliosis is present in the large majority of cases. Primitive reflexes (e.g., glabellar reflex) do not disappear over time. Electroencephalogram-proven seizures are present in approximately a quarter of patients. Patients exhibit moderate-to-severe intellectual disability with a pronounced delay in motor and language development (e.g., speech, as defined by the ability to speak one word, is present in less than 10% of cases).

Body weight (corrected for age) shows progressive deterioration over time, with the majority of patients being severely underweight (Fig. 66.2A). Gastroesophageal reflux disease is commonly encountered. Blood pressure is frequently elevated. In the context of being immobilized, tachycardia is present in a large proportion of patients, with the frequent occurrence of premature atrial and ventricular contractions (Fig. 66.2B). Also, atrial fibrillation and nonsustained ventricular tachycardia have been reported in affected children. In addition, second-degree and incomplete right bundle branch blocks have been reported in up to 12% of patients.

The median survival is 35 years, with 30% of patients dying in childhood. The main causes of death are pulmonary infections, aspiration pneumonia, and sudden death. There is a strongly increased risk for death in patients not attaining full head control compared with patients who do attain head control (Fig. 66.2C) and for young children (1–3 years of age) who are underweight compared with patients who are of normal body weight.

Biochemical evaluation reveals abnormal thyroid function tests. Although TSH concentrations are within the normal range, free and total T4 as well as rT3 concentrations are lower than normal in 90%

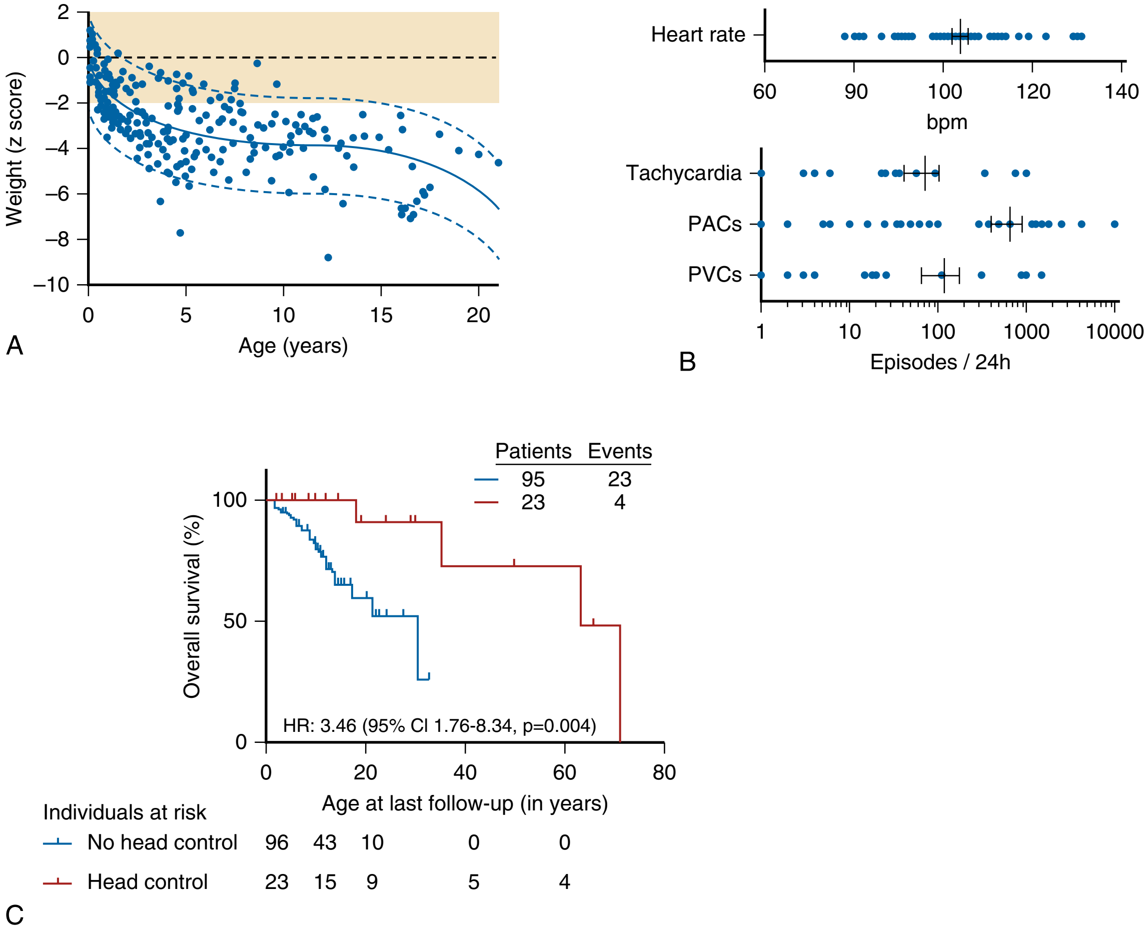

Fig. 66.2 **A,** Natural course of bodyweight change in patients with MCT8 deficiency. Blue dots represent available historical body weight measurements (n = 300) in 86 untreated patients. **B,** Mean (standard error of the mean; *black lines*) occurrence of indicated features during 24-hour cardiac monitoring. *Blue dots* represent the measurements of mean heart rate during 24 hours in 47 patients, or the frequency (per 24 hours) of indicated parameter in 45 patients (premature atrial contractions [PACs] and premature ventricular contractions [PVCs]) or 41 patients (tachycardia) with available data. **C,** Kaplan-Meier estimates of MCT8-specific survival in patients who attained head control *(red line)* by the age of 1.5 years versus those who did not *(blue line)*.

of patients, while total T3 concentrations are above normal in 95% of patients. This results in highly abnormal T3:T4 and T3:rT3 ratios. T4 concentrations obtained from neonatal screening cards were low in the majority of patients, while TSH concentrations were under 15 mU/L in all tested patients.

Serum concentrations of sex hormone–binding globulin were elevated in most patients. Serum alanine aminotransferase, aspartate aminotransferase, and glutamyl transferase concentrations were mildly elevated in a large proportion of patients.

Magnetic resonance imaging (MRI) scans of the brain consistently show a global delay in myelination,[33,35] which improves over age. In addition, diffuse atrophy is present with concomitant dilatation of the ventricles. Magnetic resonance spectroscopy shows an increased choline peak and a decreased N-acetyl aspartate peak, which is compatible with aberrant myelination and general atrophy.

Molecular Genetics. The *SLC16A2* gene is located on the X chromosome and encodes two possible translation start sites, resulting in a long MCT8 isoform of 613 amino acids or a short isoform of 539 amino acids. The relevance of the extended intracellular N-terminal part of the long isoform is unclear. MCT8 consists of 12 TMDs that are organized in two symmetric bundles of six TMDs linked through a large intracellular loop.[1] Approximately half of the mutations are missense mutations, all of which are located in the TMDs. The remainder of the mutations include deletions and nonsense mutations resulting in truncated proteins. An overview of mutations is shown in Fig. 66.3.

For certain mutations (e.g., large deletions, early premature stop codons) it can be inferred that no functional MCT8 is produced. *In vitro* thyroid hormone transport capacity assessment of missense mutations indicates that the majority render the transporter fully inactive, with some mutations showing residual transport activity.[1,36] Although the definitive genotype–phenotype relationship remains to be elucidated, individuals that have MCT8 mutations with residual thyroid hormone transport appear to have a less severe phenotype, including less affected motor and cognitive abilities.

Female carriers have FT4 concentrations between those seen in affected patients and healthy individuals,[37] and the majority appear asymptomatic. However, the occurrence of minor symptoms in female carriers has never been systematically studied and thus remains speculative. MCT8 deficiency mainly occurs in males due to the X-linked inheritance. In rare cases, traits of MCT8 deficiency can be present in females as a result of chromosomal translocations and unfavorable nonrandom X inactivation in female carriers.[38]

Fig. 66.3 Genetic pathogenic mutations in *SLC16A2*, the gene encoding MCT8.

Mechanisms of Disease. The mechanisms underlying the phenotypic features have been investigated in different animal models.

Mct8 KO mice have elevated T3, decreased T4, and normal or slightly increased TSH concentrations compared with wild-type mice, replicating human thyroid function tests. Different mechanisms may contribute to the abnormal endocrine profile. First, the increased T3:T4 ratio suggests that thyroid hormone metabolism is changed. Dio1 activity is increased in the liver and kidney of *Mct8* KO mice, and additional inactivation of *Dio1* in *Mct8* KO (*Mct8/Dio1* double KO mice) normalizes the T3:T4 ratio, indicating the prominent role of Dio1 to the disturbed T3:T4 ratio.[39] However, selective inactivation of hepatic Dio1 activity did not normalize thyroid hormone concentrations in *Mct8* KO mice.[40] Second, the thyroid gland may contribute to the abnormal serum thyroid hormones. Intrathyroidal T4 and T3 concentrations are increased in *Mct8* KO mice, and the ability to secrete T4 is reduced.[41,42] Those observations indicate a role of MCT8 in releasing thyroid hormones into the bloodstream, which is compatible with the basolateral expression of MCT8 in thyrocytes. The partial retention of T4 in the thyroid may lead to an enhanced conversion to T3 by thyroidal Dio1 activity. However, athyroid *Pax8/Mct8* KO mice substituted with T4 had similar low T4 concentrations to *Mct8* KO mice, indicating that extrathyroidal mechanisms are involved. Third, T4 accumulates in kidneys of *Mct8* KO mice; however, it is unclear how the absence of MCT8 in the kidney contributes to the endocrine phenotype.

In *Mct8* KO mice, thyrotropin-releasing hormone (TRH) is upregulated in the hypothalamus,[41] possibly reflecting the inability of locally produced T3 to exert its effects on the hypophysiotropic TRH-producing cells. The pituitary is relative insensitive towards thyroid hormone, although the precise mechanisms are unknown.[41,42]

The elevated T3 concentrations in *Mct8* KO mice have adverse effects on energy metabolism, with increased energy expenditure, associated with a lower fat mass and enhanced glucose metabolism in muscle as result.[43] In addition, *Mct8/Oatp1c1* KO mice have episodes of tachycardia and bradycardia, possibly linked to defective input from the central nervous system.[44]

Although *Mct8* KO mice mimic the endocrine phenotype seen in patients, no neurological phenotype was observed. The double *Mct8/Oatp1c1* KO mouse model did, however, result in cerebral hypothyroidism associated with abnormal brain development due to defective transport of T3 and T4 across the BBB as described in patients.[45] Patient-derived induced pluripotent stem cells differentiated towards endothelial cells of the BBB also indicate the importance of MCT8 for the translocation of both T4 and T3 across the BBB.[46] In addition to the expression at the BBB, MCT8 is expressed in other cells of the brain (e.g., neurons, astrocytes, and tanycytes lining the third ventricle).[47] Although the functional role in those cells remains to be elucidated, data indicate that MCT8 has a cell-autonomous role in neurons.[48]

The clinical phenotype is a composite of tissues with different thyroid states. Depending on the expression of MCT8 and other thyroid hormone transporters, tissues either have insufficient thyroid hormone concentrations (e.g., brain) or are exposed to toxic T3 concentrations (e.g., liver and muscle). With MCT8 being expressed at the BBB and in neural cells, defective MCT8 precludes entry of thyroid hormone into the brain, resulting in abnormal cerebral thyroid hormone concentrations. Postmortem histological analysis of brain regions in patients with MCT8 deficiency are consistent with a hypothyroid state.[49] Therefore, given the critical role of thyroid hormone for many processes involved in brain development, absence of MCT8 will result in abnormal neurodevelopment. The strongly elevated serum T3 levels cause thyrotoxic signs and symptoms in tissues that are not dependent on MCT8; the clinical sequelae predispose to significant morbidity and mortality.

Clinical Management. Supportive care is recommended to address all common clinical features. The occurrence of contractures and scoliosis warrants referral to rehabilitation physicians early in life. Physiotherapists should acknowledge the dominance of the movement disorder in childhood compared with a stronger spastic component later in life. Empirical symptomatic treatment can be initiated on demand. Seizures may warrant antiepileptic drugs, and treatment with drugs to alleviate dystonia and drooling (e.g., anticholinergic drugs) can provide relief, but usually to a limited extent. The progressive decline in body weight due to the thyrotoxicosis and difficulties in swallowing, as well as the strong association with mortality, calls for close monitoring of nutritional status by dieticians, with percutaneous endoscopic gastrostomy feeding often required to meet daily calorie requirements. Given the high prevalence of cardiovascular risk factors, referral for cardiac evaluation is indicated.

Levothyroxine replacement therapy has been offered empirically in many patients because of suspected central hypothyroidism (i.e., low serum FT4 concentrations with normal TSH concentrations). Typically, this approach is ineffective in normalizing FT4 concentrations, and rather aggravates the elevated serum T3 concentrations due to immediate conversion of T4 to T3.[1] One case report has been described in which prenatal intraamniotic treatment with a high dosage of levothyroxine improved neurodevelopment.[50]

The combinatory therapy of propylthiouracil (PTU) (but not methimazol) with levothyroxine replacement can improve features of peripheral thyrotoxicosis.[51,52] This strategy can have clinical benefits, although effects on neurodevelopment are not expected. In addition, PTU is associated with a risk of severe hepatotoxicity. Accordingly, PTU is not recommended as therapy for hyperthyroidism, and its use, particularly in children, is discouraged by current guidelines. The unfavorable safety profile of PTU is particularly relevant in the context of the frequent need to use other drugs (e.g., antiepileptic drugs) with hepatotoxic side effects in MCT8-deficient patients. Therefore, risks and benefits counseling is appropriate if this therapy is considered, in particular the lifelong need for PTU.

Effective therapy should aim to alleviate toxic effects of thyroid hormone in peripheral tissues while improving decreased thyroid hormone signaling in brain. Different possibilities have been explored as therapeutic options for MCT8 deficiency. Preclinical studies have investigated restoring MCT8 function through gene therapy and through application of chaperone molecules that have the capacity to rescue misfolded MCT8 mutants.[53,54] The clinical utilization of those potential options needs to be further elucidated.

Thyromimetic molecules that act as thyroid hormone receptor agonist, but whose cellular entry is not dependent on MCT8, have the potential to prevent or even reverse the neurological phenotype in patients with MCT8 deficiency. Also, such T3 analogs can negatively regulate TSH concentrations, thereby reducing endogenous thyroid hormone production and secretion. The T3 analogs Triac (triiodothyroacetic acid), DITPA (diiodothyropropionic acid), and sobetirome and the sobetirome prodrug Sob-AM2 have been investigated in preclinical studies, with varying positive effects on different outcomes.[55-58] Clinical experience with DITPA application in four children with MCT8 deficiency has been reported.[59] Serum T3 and sex hormone–binding globulin concentrations improved in all patients, although no consistent effect on body weight was observed. Triac treatment was evaluated in 46 (pediatric and adult) patients in an international trial.[60] Triac treatment induced a strong and sustained reduction of the elevated T3 concentrations and, consequently, improved biochemical markers of thyroid hormone action in different tissues. Also, sustained improvements in clinically relevant outcomes including body weight for age, heart rate, and blood pressure were observed. Severe underweight and cardiovascular dysfunction are important clinical sequelae of chronic peripheral thyrotoxicosis, causing substantial morbidity and mortality in patients with MCT8 deficiency. Amelioration of the thyrotoxicosis with Triac treatment could benefit patients with MCT8 deficiency, irrespective of their age. Ongoing studies may reveal if Triac administration early in life can improve the neurocognitive phenotype.

KEY POINTS

- Mutations in the X-linked thyroid hormone transporter MCT8 cause profound neurodevelopmental delay due to cerebral hypothyroidism, as well as a wide range of severe clinical sequelae secondary to chronic peripheral thyrotoxicosis. 3,5,3′-tri-iodothyronine analog (e.g., Triac) therapy has the potential to ameliorate key clinical features of this rare disorder.

Organic Anion Transporting Polypeptide 1C1 Deficiency. One individual with a homozygous mutation in *OATP1C1* has been reported.[61] Cognitive and motor function were delayed in childhood, followed by the progressive loss of attained skills, resulting in the absence of verbal communication and spasticity, as well as difficulties in swallowing. Profound cold intolerance was noted, with normal serum thyroid function parameters. (^{18}F)-fluorodeoxyglucose–positron emission tomography scan showed a largely decreased glucose metabolism, and MRI examination of the brain showed progressive atrophy in the cerebral cortex, subcortical white matter, and cerebellum. The homozygous D252N mutation had decreased cellular T4 transport capacity due to impaired plasma membrane localization.

Brain T4 concentrations were reduced in *Oatp1c1* KO mice but did not result in neurological abnormalities, probably due to redundancy of other thyroid hormone transporters, including Mct8.[62] Zebrafish *oatp1c1* KOs showed abnormal locomotor changes, alterations in radial glial cell development, and shorter neuronal axons.[63] Of note, *oatp1c1* KO zebrafish demonstrated a large goiter, which was fully reversed in the presence of Triac, but not by T3 or T4. As OATP1C1 expression is different in human versus in rodents and fish, it is unclear to what extent findings in animal models can be extrapolated to humans.[1] Moreover, it is unclear if the clinical phenotype can be fully attributed to dysregulation of thyroid hormone in the brain. Possibly, based on the OATP1C1 expression in astrocytes, impaired T4 accumulation in astrocytes results in less conversion to T3 by the DIO2 present in those cells. However, with OATP1C1 present in other cell types as well, defective OATP1C1 in such cells may also contribute to the clinical phenotype.

The combination of levothyroxine and Triac resulted in improvement of alertness and also of swallowing.[61] Future identification of more patients with *OATP1C1* mutations will help to define the clinical features and to understand the mechanisms of disease underlying OATP1C1 deficiency.

DISORDERS OF THYROID HORMONE METABOLISM

Iodothyronine Deiodinase I Deficiency

Two unrelated families heterozygous for pathogenic variants in *DIO1* mutations have been identified.[22] In the first family, a 3-year-old girl with Down syndrome, from nonconsanguineous parents of Hispanic origin, had slightly elevated serum TSH and was positive for thyroperoxidase antibodies, often associated with Down syndrome.[23] The second proband, from nonconsanguineous Jewish parents, was also referred to the clinic with resistance to TSH. Genetic analysis identified in each family one rare heterozygous and one predicted pathogenic variant in *DIO1*: N94K and M201I, respectively. Multiple family members were found to be heterozygous for the *DIO1* mutations, and all affected individuals showed no obvious abnormalities other than characteristic thyroid tests with elevated serum rT3 concentrations and rT3/T3 ratios compared with unaffected family members. One family was investigated in more detail and exhibited normal liver enzymes (alanine aminotransferase and aspartate aminotransferase), blood urea nitrogen, and creatinine concentrations. However, total cholesterol concentrations were high/normal to very high in the affected individuals, and need to be considered as a potential parameter for identifying patients.

In vitro activity assays suggest that the mutations affect substrate affinity and enzyme velocity compared with the wild-type enzyme. The underlying mechanism for the abnormal serum thyroid hormone levels in heterozygous *DIO1*-patients is thought to be haploinsufficiency, similar to what is described in two mouse models. Dio1 deficiency, naturally occurring in the C3H/He mice strain, resulted in elevated serum rT3 level and rT3/T3 ratio.[24,25] These results were confirmed in the genetically engineered heterozygous *Dio1*-deficient mice,[22] with the homozygous *Dio1* KO exhibiting raised T4 and rT3 with normal T3 and TSH levels.[9]

Both Asn94 and Met201 are highly conserved amino acids within the DIO family over different species, suggesting an important function. In the absence of a protein structure for DIO1, the effect of these mutations can be assessed using a model generated from the highly homologous DIO3 structure (Fig. 66.4). The N94K and M201I mutations are fairly conservative, both in size and polarity, and their positions are not expected to result in major changes in the overall structure, but may affect specific local function of DIO1. Met201 is located near the substrate-binding and catalytic activity core of the enzyme, with His174, part of the proposed proton transfer chain for reductive 5'-deiodination, in close proximity. Asn94 is situated close to the hinge segment, between the TMD and the globular substrate-binding domain.

KEY POINTS

- The human deiodinase genes have been subject to investigation for a long time; however, only pathogenic genetic defects in DIO1 have recently been described. Thyroid tests show elevated serum 3,5′,3′-tri-iodothyronine concentrations and 3,5′,3′-tri-iodothyronine/3,5,3′-tri-iodothyronine ratio, with a suggestion that total cholesterol concentrations are elevated.

SBP2 Deficiency

Clinical Phenotype. Compound heterozygous or homozygous *SECISBP2* defects have been described in patients from diverse ethnic backgrounds, exhibiting similar clinical phenotypes[29] (Table 66.3). Most cases were diagnosed in childhood with growth retardation (e.g., failure to thrive, short stature, delayed bone age) and developmental delay (e.g., delayed speech, intellectual and motor coordination deficits) as common features that brought probands to clinical attention.

The biochemical phenotype in all affected cases suggests a defect in T4 to T3 conversion, with raised circulating FT4, normal to low free T3 (FT3), raised rT3 concentrations, and normal or slightly high TSH concentrations with no noticeable goiter.[64] This pattern reflects deficiency of all three selenocysteine-containing DIO enzymes, and, consistent with this hypothesis, higher than normal amounts of exogenous T4 are required to suppress TSH levels, whereas the response to T3 is normal.[65] Such abnormal thyroid function, together with low plasma selenium levels, reflecting decreased levels of SELENOP and GPX3, which constitute the major circulating selenoproteins, provides the biochemical signature that facilitates identification of putative cases of SBP2 deficiency due to *SECISBP2* mutation.

Fatigue and muscle weakness, at least partially due to progressive rigid spine muscular dystrophy affecting axial and proximal limb muscles, are recognized features in several patients and are very similar to the phenotype of selenoprotein N–deficient myopathies.[66] Circulating skeletal muscle–specific creatine kinase levels can be elevated, and selective fatty infiltration of the muscle groups (adductor, biceps femoralis) is visible on MRI scan even in childhood, prior to onset of clinical symptoms. Histological analysis shows type 1 oxidative fiber predominance and areas of sarcomere disorganization, termed minicores, in muscle from the *SECISBP2*-mutated adult proband.[67] More marked abnormalities and symptoms in adult patients suggest that the myopathy is progressive and lead to reduced lung function (expiratory and inspiratory flow; total vital capacity), possibly requiring positive pressure ventilatory support.

Mild bilateral high-frequency sensorineural hearing loss is seen in some patients, with adults being most severely affected and sometimes requiring hearing aids, perhaps reflecting a progressive course.

Increased whole-body fat mass, with the excess adipose tissue being predominantly subcutaneous with relatively normal visceral fat, and high circulating adiponectin, possibly of peripubertal onset, have been noted in some cases. Paradoxically, these features are associated with low intrahepatic lipid, a favorable blood lipid profile, and preserved or enhanced tissue insulin sensitivity with possible propensity to spontaneous hypoglycemia.[67]

One adult *SECISBP2*-mutated patient was investigated in great detail, and at presentation (age 35 years) exhibited additional features beside the phenotypes described already, including azoospermia (spermatogenic maturation arrest with preservation of early cell types, e.g., spermatogonia and spermatocytes, but lack of mature spermatids and spermatozoa), skin photosensitivity, severe Raynaud disease (digital vasospasm), rotatory vertigo, and reduced red blood cell and total lymphocyte counts, with impaired mononuclear cell cytokine secretion and T-cell proliferation.[67] Decreased circulating white blood cells and neutrophils were also described in a Japanese patient.[68] An additional characteristic in patients is that many phenotypes (e.g., metabolic phenotype, hearing, muscle weakness, photosensitivity) worsen with advancing age.

Molecular Genetics. Selenium is an essential micronutrient that is incorporated as the amino acid Sec into at least 25 human selenoproteins. Most selenoproteins function as oxidoreductases, with the Sec residue involved in catalytic activity, and recognized functions include maintenance of redox potential, regulating redox sensitive biochemical pathways, protection of genetic material, proteins, and membranes from oxidative damage, metabolism of thyroid hormones, regulation of gene expression, and control of protein folding.[69,70] Biosynthesis of selenoproteins requires an UGA codon within its mRNA to be recoded as the amino acid Sec, preventing its recognition as a premature stop signal. This process is achieved via unique Sec-insertion machinery comprising cis-acting SECIS elements located in the 3′ untranslated region of all selenoprotein mRNAs and the UGA codon, interacting with transacting factors (SECISBP2, Sec tRNA–specific eukaryotic elongation factor and Sec-tRNA$^{[Ser]Sec}$) (Fig. 66.5).[29,70]

From the early stages of selenoprotein research it was clear that dietary selenium intake affects systemic selenium status and selenoprotein expression. However, not all selenoproteins are affected in the same way, with synthesis of housekeeping selenoproteins (e.g., TrxR1, TrxR3, GPx4) being less affected by reduced circulating selenium levels than stress-related selenoproteins (e.g., GPx1, GPx3, SEPW1). Such differential preservation of selenoprotein expression is attributed to the existence of a "hierarchy of selenoprotein synthesis," the underlying molecular basis of which is unclear.[71]

SECISBP2 is an obligate and limiting factor for biosynthesis of selenoproteins and is a large (854 amino acids, 120 kDa) protein. The first 400 N-terminal residues are dispensable for its function *in vitro*, whereas the C-terminal region (amino acids 399–784) is both necessary and sufficient for binding to the SECIS element in the selenoprotein RNA and Sec incorporation. Alternative splicing events and multiple ATG start codons for initiation of translation have been described for SECISBP2, generating different protein isoforms.[72] These events alter content of the dispensable N-terminal region, but not the essential C-terminal domain and are thought to play a role in regulation of SECISBP2-dependent Sec incorporation and the hierarchy of selenoprotein expression *in vivo*.

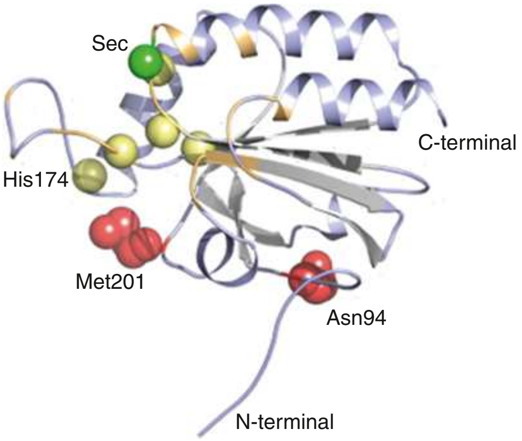

Fig. 66.4 Structural model of the deiodinase 1 with positioning of the mutated amino acids. The model represents the globular, active domain of deiodinase 1 (DIO1). The amino acid selenocysteine is shown in *green*, amino acids described to be involved in proton transfer during reductive 5-deiodination are in *yellow*, those involved in substrate binding and catalytic activity in *orange,* and the two affected amino acids (Met201 and Asn94) are in *red*. The C-terminal and N-terminal ends of the protein are indicated, with the latter linking to the transmembrane domain. The model was generated using the phyre2-server[101] and is based on the crystal structure of DIO3 (protein data bank [PDB]: 4TR3 and 4TR4[26]).

Homozygous or compound heterozygous mutations in *SECISBP2* have been described in 13 individuals from 11 families (Table 66.3). Consistent with a recessive mode of inheritance, heterozygous individuals do not present with any of the described phenotypes. Most *SECISBP2* mutations identified to date are premature stop codons, resulting in absence of full-length SECISBP2 protein. However, for premature stops located in the N-terminal part of the protein, initiation of translation from alternative, downstream ATG codons permits low-level synthesis of shorter SECISBP2 isoforms.[67,73,74] Some premature stop mutations are situated downstream of Met300 and may completely eliminate synthesis of functional protein. Conversely, stop mutations (e.g., R770X, Q782X), distal to the minimal functional domain might generate C-terminally truncated proteins whose functions remain partially intact (Fig. 66.6). In one patient with defective mRNA splicing due to an intronic mutation IVS8ds+29G>A,[64] expression of the correctly spliced transcript was only reduced by 50%, and it is possible that a similar mechanism operates with other splice site mutations, resulting in some preservation of normally spliced SECISBP2 mRNA.

Three missense SECISBP2 mutations (R540Q, E679D, and C691R) are situated in the RNA-binding domain of the minimal functional protein. The R540Q mutation fails to bind only a subset of SECIS-elements, and a mouse model revealed a tissue-specific pattern of SECISBP2 protein expression, correlating with varying loss or preservation of synthesis of different selenoproteins.[64,75,76] The C691R mutation is subject to enhanced proteasomal degradation,[67] confirmed in a mouse model, which also suggests that the C691R mutant is unable to bind RNA and is nonfunctional.[76] The E679D mutation is predicted to be deleterious (PolyPhen-2 algorithm score of 0.998), possibly affecting its binding to RNA, but this has not been investigated.[73]

With only a small number of patients described, *SECISBP2* mutations identified hitherto are uniformly distributed, with no particular mutation "hot spots" in the protein, although most result in a premature stop in the dispensable N-terminal region (Fig. 66.6). All patients described to date have at least one allele that either directs synthesis of SECISBP2 at reduced levels or directs synthesis of a partially functional SECISBP2, due to synthesis of shorter N- or C-terminally truncated

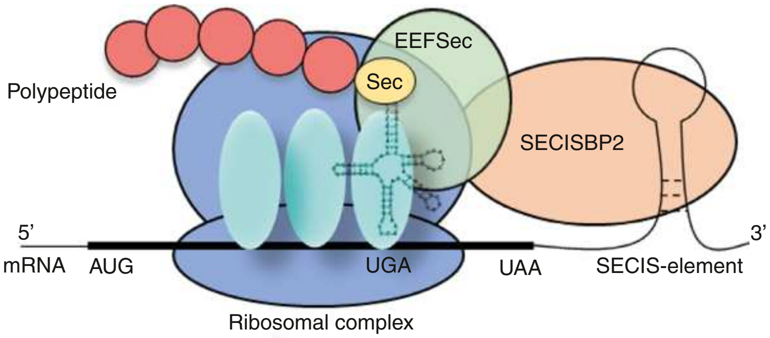

Fig. 66.5 Mechanism of selenoprotein biosynthesis. The 3′ untranslated region of selenoprotein mRNAs contains a stem-loop RNA structure (SElenoCysteine Insertion Sequence element) that interacts with a multiprotein complex which includes SECISBP2 and selenocysteine (Sec)-specific elongation factor. This enables ribosomal recruitment of a specific transfer RNA (tRNA$^{[Ser]Sec}$) to the recoded UGA codon, enabling Sec incorporation into the nascent polypeptide. Failure of this mechanism results in miscoding of the UGA as a stop codon, terminating protein synthesis.[70]

TABLE 66.3 **Human *SECISBP2* Mutations**

Family	Mutation	Protein Change	Alleles Affected	Suggested Mechanism	Ethnicity
A	c.1619 G>A	R540Q	Homozygous	Predicted to affect SECIS and ribosome binding	Saudi Arabian

N/A, Not available; *SNP*, single nucleotide polymorphism; SECIS, SElenoCysteine Insertion Sequence.

forms of the protein (Table 66.3), suggesting that they are hypomorphic rather than completely null for loss of gene function. Nevertheless, because SECISBP2 is rate-limiting for Sec incorporation, reduction in functional SECISBP2 protein compromises selenoprotein synthesis. The small number of patients described from different ethnic and geographical backgrounds, often with compound heterozygous mutations whose functional consequences have not been defined, together with limited knowledge of their phenotypes, makes it impossible to assess the effect of a specific *SECISBP2* mutation or its correlation with the severity of phenotype.

Mechanisms of Disease. Disruption of SECISBP2 function prevents appropriate Sec incorporation into most if not all selenoproteins, resulting in a multisystem disorder. Some clinical phenotypes are attributable to deficiencies of particular selenoproteins, while others may have a complex, multifactorial basis, possibly due to unbalanced oxidoredox and/or protein folding pathways, reflected in increased cellular oxidative stress measured in patients' cells, or unknown function of selenoproteins. SECISBP2 is essential for survival, as murine *Secisbp2* deletion is embryonic lethal.[77] Accordingly, conditional and tissue-specific murine *Secisbp2* or specific selenoprotein KO models have provided informative insights into pathogenesis of the human disorder.

Selenocysteine is present in the active center and required for enzymatic activity of all three iodothyronine DIOs, and, consonant with *SECISBP2* deficiency, DIO2 activity was reduced in fibroblasts from one family.[64] DIO2 converts T4 to T3, and its activity can change very rapidly, as its half-life (approximately 20 minutes) is much shorter (15-fold) than that of DIO1 and DIO3. The combination of reduced DIO2 synthesis, together with its short half-life, likely explains its low activity in patient cells. The thyroid phenotype of *SECISBP2*-mutated patients is most closely recapitulated by a murine *Dio1* and *Dio2* double KO,[13] suggesting that it is mediated by combined, partial deficiency of both DIOs. However, unlike human *SECISBP2* patients, both double *Dio1/Dio2* and triple *Dio1/Dio2/Dio3* KO mice have relative normal serum T3 levels, suggesting that a combination of partial deficiency of all three DIOs and improper fine-tuning of specific DIO expression mediates the abnormal thyroid function test pattern seen in this disorder.

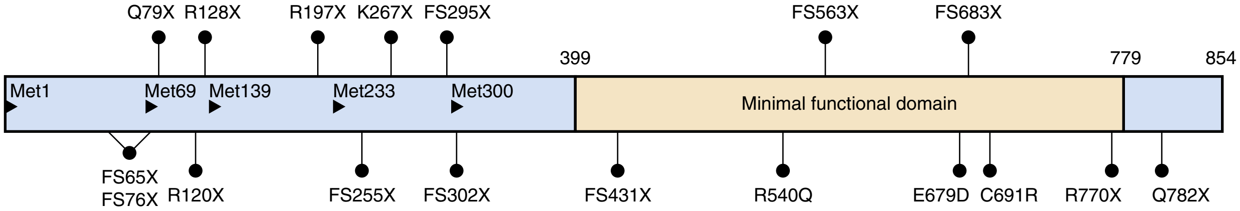

Fig. 66.6 Schematic representation of the SECISBP2 protein with the location of mutations. The position of all mutations is superimposed, and details of mutations in patients are shown in Table 66.3. Neither homozygous or different, compound heterozygous, mutation combinations are predicted to completely eliminate synthesis of the minimal functional domain (amino acids 399–779, *shaded*) of SECISBP2. Internal methionine residues from which translation of shorter SECISBP2 protein isoforms can be initiated are shown.

The thyroid hormone biochemical phenotype seen in patients is recapitulated in an inducible mouse model of *Secisbp2* deficiency, albeit associated with more robust increase in serum TSH levels.[78]

Growth retardation and developmental delay are the commonest symptoms in *SECISBP2*-mutated patients, and the pathogenesis is probably multifactorial, with no clear link to deficiency of a single selenoprotein or pathway. Growth retardation is a recognized feature in *Dio2* and *Dio3* null mice,[11,12] suggesting that the human phenotype is, at least in part, mediated by abnormal thyroid hormone metabolism. Consistent with this notion, treatment of SECISBP2-deficient children with T3 alone (family C, F) or in conjunction with growth hormone (family G) resulted in catch-up growth. Neuron-specific *Secisbp2* KO mice present with growth retardation, with unclear mechanistic basis.[79] Selective depletion of multiple selenoproteins in murine osteochondroprogenitor cells results in epiphyseal abnormalities and chondronecrosis,[80] suggesting an important, cell-autonomous role for selenoproteins in skeletal development. However, in a single *SECISBP2*-mutated case (family E), radiological skeletal survey and bone mineral density were found to be normal.

Axial muscular dystrophy, leading to fatigue and muscle weakness, is a musculoskeletal phenotype highly analogous to that seen in patients with a myopathic disorder (rigid spine muscular dystrophy) due to mutations in selenoprotein N.[81] Motor incoordination in some *SECISBP2*-mutated patients could be due to selenoprotein N myopathy and axial muscle weakness. However, neuron-specific *Secisbp2* null mice[79] also exhibit an obvious locomotor phenotype, together with degenerative loss of PV+/Gad67+ interneurons in basal ganglia, providing a possible alternative explanation for the movement disorder and raising the possibility that this phenotype is progressive.

Azoospermia with spermatogenic maturation arrest described in the adult *SECISBP2*-mutated patient can be linked with deficiency of three selenoproteins (mGPX4, TXNRD3, SELV), with recognized roles in spermatogenesis. Mitochondrial GPX4 (mGPX4) is a structural component of the mitochondrial capsule in the midpiece of spermatozoa,[82] with murine mGpx4 KO resulting in male infertility,[83] and reduced human seminal mGPX4 activity correlates with oligospermia.[84] TXNRD3 is highly enriched in spermatids and may catalyze protein disulfide bond isomerization in sperm development.[85] Human SELV expression is known to be testis-restricted, but its function is unknown.[86] Consistent with the role of mGPX4 and TXNRD3 in latter spermatogenic stages, testicular histology in the adult *SECISBP2*-mutated patient showed maturation arrest, with preservation of early cell types (e.g., spermatogonia and spermatocytes) but lack of mature spermatids and spermatozoa. Male and female infertility are described in a mouse model of *Secisbp2* deficiency.[78]

The bilateral high-frequency sensorineural hearing loss in *SECISBP2*-mutated cases could be due to DIO2 deficiency, with hearing loss and retarded cochlear development being recognized features in *Dio2* null mice,[11] whereas cochlear anatomy is normal and DIO2 activity only partially reduced in human *SECISBP2*-mutated cases. An alternative hypothesis links hearing loss to damage mediated by elevated cellular reactive oxygen species (ROS), similar to the noise-induced hearing loss observed in *Gpx1* null mice.[87] ROS-mediated cochlear damage can be cumulative,[88] which could explain the progressive nature of hearing loss, resulting in a more severe deficit in the older, adult, *SECISBP2*-mutated case.

Several other recorded phenotypes (enhanced insulin sensitivity and increased adipose mass, reduced red blood cell and total lymphocyte counts, cutaneous photosensitivity, developmental delay, growth and skeletal phenotype) probably have a multifactorial basis, comprising a combination of abnormal thyroid hormone metabolism, loss of antioxidant and endoplasmic reticulum stress defense pathways, and deficiency of specific selenoprotein(s), resulting in irreparable cell and organ damage due to cumulative cellular stress. Many studies in mouse models and in humans provide a substantial body of evidence to suggest a link between selenoproteins and most of these phenotypes.[67,89-92]

It is conceivable that cumulative cellular stress (oxidative, endoplasmic reticulum) and irreparable cell damage could also predispose to other phenotypes (e.g., premature ageing, cancer) that have not yet manifested in the relatively young cohort of patients identified hitherto.

Clinical Management. Oral selenium supplementation in some *SECISBP2*-mutated patients raised total serum selenium levels, but without clinical[74,93,94] or biochemical (circulating GPXs, SELENOP, thyroid hormone metabolism) effect.[95] This is probably because the disorder involves defective incorporation of selenium into the selenoproteins, rather than deficiency of this trace element *per se*, although the effect could be mutation-dependent.

Treatment of some probands with T3 alone (T4 was not effective in one case) or in combination with growth hormone resulted in some improvement in growth, development, and bone maturation, suggesting that T4 or T3 treatment at younger age might be beneficial.

Treatment of proband G with a combination of alpha tocopherol (vitamin E) and T3 resulted in the most promising response. Serum levels of products of lipid peroxidation decreased, FT4 and FT3 concentrations ameliorated, and circulating white blood cells and neutrophils increased, all of which were reversed after treatment withdrawal.[68] These observations suggest that treatment with antioxidants, to compensate for loss of antioxidant selenoproteins, is a possible therapeutic option for this disorder. However, due to limited number of *SECISBP2*-mutated cases and a paucity of evidence, clinical trials of antioxidants, perhaps in combination with T3 and growth hormone, are warranted, to develop a rational therapeutic approach in this disorder.

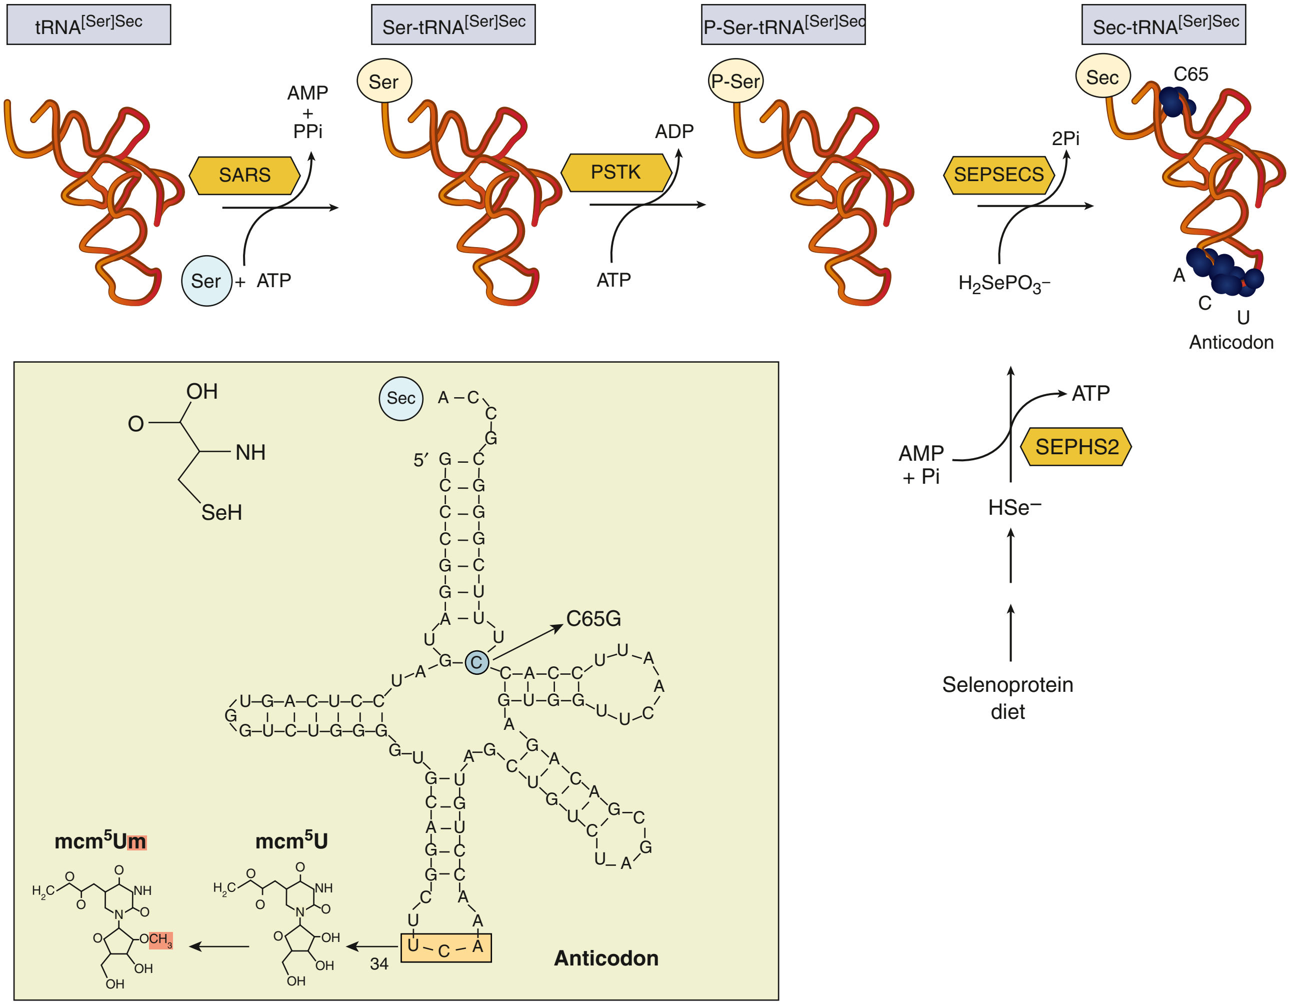

Fig. 66.7 Pathway of Sec-tRNA$^{[Ser]Sec}$ synthesis and clover leaf model of Sec-tRNA$^{[Ser]Sec}$. **A,** Synthesis of selenocysteine (Sec) occurs using its own tRNA, starting with attachment of serine to tRNA$^{[Ser]Sec}$ by seryl-tRNA synthetase (SARS). This residue is phosphorylated by phosphoseryl-tRNA kinase (PSTK), and the phosphoserine is subsequently converted to Sec-tRNA$^{[Ser]Sec}_{mcmU}$ by Sep (O-phosphoserine) tRNA:Sec tRNA synthase (SEPSECS) using selenophosphate. The selenophosphate is synthesized from selenide, originating from diet and degradation of Sec-containing proteins, by selenophosphate synthetase 2 (SEPHS2).[70] The position of the mutated base (C65) and the anticodon bases (U34, C35, and A36) are highlighted as *black spheres* in Sec-tRNA$^{[Ser]Sec}$. **B,** The amino acid Sec is depicted, as well as a clover leaf model of Sec-tRNA$^{[Ser]Sec}$ with the position of the mutated base (C65G, *ringed*) and the modification on uridine 34 in the anticodon *(boxed)* to Sec-tRNA$^{[Ser]Sec}$ $_{mcm5U}$ or Sec-tRNA$^{[Ser]Sec}$ $_{mcm5Um}$ by an unidentified Um34 methylase.[99,100]

Sec-tRNA$^{[Ser]Sec}$

The amino acid Sec is different from other amino acids in that it is synthesized using its own tRNA, tRNA$^{[Ser]Sec}$, encoded by *TRU-TCA1-1*, via a well-described pathway involving SEPSECS (Fig. 66.7).[70] Two major isoforms of the mature Sec-tRNA$^{[Ser]Sec}$ have been identified, containing either 5-methoxycarbonyl-methyluridine (mcm^{5}U) or its methylated form, 5-methoxycarbonylmethyl-2’-O-methyluridine (mcm^{5}Um), at position 34 (Fig. 66.7). Uridine 34 is located in the anticodon loop, and its methylation may contribute to stabilization of the codon–anticodon interaction. These Sec-tRNA$^{[Ser]Sec}$ subtypes have a role in controlling the hierarchy of selenoprotein synthesis, with production of essential, cellular housekeeping selenoproteins (e.g., TXNRDs, GPX4) being dependent on the mcm^{5}U isoform and cellular, stress-related selenoprotein (e.g., GPX1, GPX3) synthesis requiring the mcm^{5}Um isoform.[96,97]

A single patient homozygous for a single nucleotide change (C65G) in *TRU-TCA1-1* has been identified (Fig. 66.7)[98] and exhibits a similar clinical and biochemical phenotype (abdominal pain, fatigue and muscle weakness, raised FT4, normal T3, raised rT3 and TSH, low plasma selenium concentrations) to that seen in patients with *SECISBP2* deficiency. However, the pattern of cellular expression of selenoproteins in the two disorders differs, with synthesis of housekeeping selenoproteins (e.g., TXNRDs, GPX4) being preserved in the *TRU-TCA1-1* case, while levels of cellular stress–related selenoproteins (e.g., GPX1, GPX3) were similarly reduced in both disorders.

In the proband with the *TRU-TCA1-1* C65G mutation, lower total tRNA$^{[Ser]Sec}$ expression with disproportionately greater diminution in Sec-tRNA$^{[Ser]Sec}$ mcm^{5}Um levels were found. The mechanism of this is unresolved, with possibilities including effects of the mutation on stability or posttranscriptional maturation of Sec-tRNA$^{[Ser]Sec}$ or the stability of the Sec-tRNA$^{[Ser]Sec}$–SEPSECS complex. Similar to differential preservation of selenoprotein synthesis seen in murine tRNAsec mutant models,[70,96] it is thought that the low levels of tRNA$^{[Ser]Sec}$ seen in the proband are sufficient for normal synthesis of housekeeping selenoproteins, whereas diminution of Sec-tRNA$^{[Ser]Sec}$ mcm^{5}Um levels accounts for reduced synthesis of stress-related selenoproteins.

Given that systemic selenium status is known to influence relative proportions of the tRNA$^{[Ser]Sec}$ isoforms, with Sec-tRNA$^{[Ser]Sec}$ mcm^{5}Um being low in selenium deficiency but enriched in the selenium-replete state,[96,99,100] it is possible that altering the selenium status of the patient with selenium supplementation to restore particular selenoprotein deficiencies, with careful monitoring for toxicity, could represent a rational therapeutic approach.

KEY POINTS

- Selenium is an essential micronutrient incorporated into at least 25 human selenoproteins as the amino acid selenocysteine (Sec), and SECISBP2 is an obligate and limiting factor for their biosynthesis. Sec incorporation is also dependent on its own transfer RNA (tRNA[Ser]Sec), encoded by TRU-TCA1-1.
- Individuals with SECISBP2 defects exhibit a multisystem phenotype including growth retardation, fatigue and muscle weakness, sensorineural hearing loss, increased whole-body fat mass with enhanced insulin sensitivity, azoospermia, and cutaneous photosensitivity. Characteristic biochemical abnormalities in patients are raised FT4, normal to low FT3, raised rT3, and normal/slightly high thyroid-stimulating hormone, reflecting abnormal thyroid hormone metabolism due to deficiency of all three Sec-containing deiodinase enzymes and low plasma selenium levels due to deficiency of circulating SELENOP and GPX3.
- A single individual with a TRU-TCA1-1 mutation exhibits the same biochemical phenotype and some clinical features as patients with SECISBP2 defects. However, selenoprotein expression in this patient's cells differ, with relative preservation of essential housekeeping versus stress-related selenoproteins.

COMPONENTS OF THYROID HORMONE ACTION

Thyroid hormone (TH) action is mediated by the two principal THs, thyroxine (T4) and triidothyronine (T3), that are synthesized within thyroid follicular cells such that the human adult thyroid synthesizes and releases THs in a ratio of approximately 85% T4 and 15% T3. TH signaling is regulated at multiple levels (Fig. 67.1). Circulating serum binding proteins deliver T4 and T3 to tissues, and binding proteins help to ensure consistent hormone delivery throughout the body. Higher hormone levels are generally correlated with increased TH response. However, there are differences in availability of hormone in peripheral tissues that are the consequence of variations in cellular transport and local conversions of T4 to T3 by the deiodinase enzymes.[4] In some tissues, as best characterized in the brain, this tissue uptake is regulated by specific TH transporters.[2,3] TH receptors (TRs) mediate the majority of TH signaling by nuclear actions and regulate gene expression. Tissue sensitivity is further adjusted by expression of coregulatory proteins that interact with TRs. The relative activity of these pathways, and the variation by tissue type, means that the correlation between plasma hormone levels and response is not absolute, consistent with the variety of clinical manifestations of thyroid disease. All components of TH signaling will be described, as well as the associated defects that have been reported with the various TH signaling pathways.

KEY POINTS

- Thyroid hormone signaling is influenced by ligand availability, tissue uptake, nuclear receptor isoform type, and interaction with corepressors and coactivators.

REGULATION OF LIGAND AVAILABILITY IN DEVELOPMENT AND THE ADULT

TH is required for normal brain and somatic development, and regulation of ligand availability occurs at multiple levels. While TH synthesis is covered in another chapter, it is important to note that the fetal thyroid (in particular the follicular cells) develops from anterior endoderm and is functional in context of TH synthesis in the late stages of the first trimester.[5] Until that time, the developing fetus is dependent upon maternal THs, which cross the placenta in small amounts. The importance of the maternal transfer of TH for development is best delineated by syndromes of congenital hypothyroidism, where TH synthesis is not possible.[6,7] As long as TH therapy is begun at birth, fetal development, including neurologic development, is normal. In contrast to the ligand deficiency, which is compensated by maternal TH, fetuses with rare defects in the TH transporter (monocarboxylate transporter 8 [MCT8]) are born with significant irreversible neurologic deficits due to an inability of maternal or fetal T4 to impact the brain at critical stages of development.[8]

---

*Portions of this chapter were taken from an earlier edition, authored by Dr. Fredric E. Wondisford, and these contributions are acknowledged.

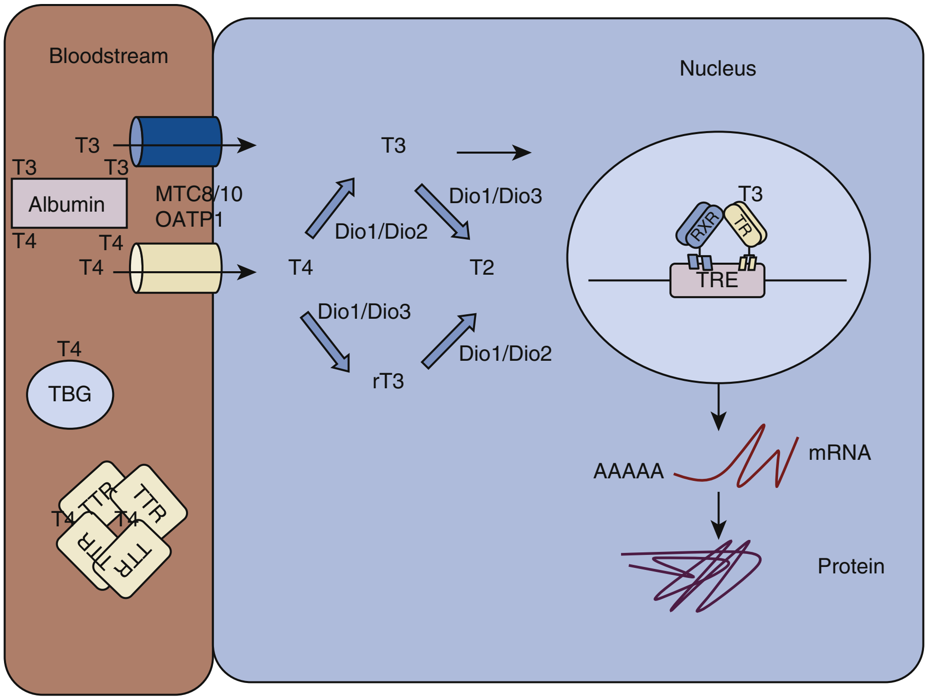

Fig. 67.1 **Triiodothyronine (T3) modulates gene expression in virtually every vertebrate.** Thyroxine (T4)/T3 circulates attached to serum proteins, including thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin. A small fraction of circulating T4 is free to be transported into the cytoplasm, where it is activated to T3 by outer-ring deiodination catalyzed by type 1 deiodinase (Dio1) or type 2 deiodinase (Dio2). The resulting T3 is thought to be diffused into the nucleus to bind the thyroid hormone receptors (TRs). Upon binding to the TRs, T3 modulates the rate of mRNA synthesis, and ultimately the protein levels of thousands of genes in virtually every cell. *RXR*, Retinoid X receptor; *TRE*, thyroid hormone response element. (From Mendoza A, Hollenberg AN. New insights into thyroid hormone action. *Pharmacol Ther*. 2017;173:135–145.)

THYROID HORMONE BINDING TO SERUM PROTEINS

TH circulates predominantly bound to serum protein, which provides a significant reservoir for distribution to target tissues (Fig. 67.1). Both major forms of TH (T4 and T3) are transported in the circulation in complex with plasma proteins.[1] The ratio of total T4 to T3 in plasma is approximately 60:1. This is higher than the 15-fold ratio of T4 to T3 that is initially secreted by the thyroid gland, because of greater plasma binding of T4 versus T3, resulting in greater clearance rates of T3. Approximately 99.98% of total circulating T4 and 99.7% of T3 form noncovalent interactions with serum proteins: mostly thyroxine-binding globulin, but to a lesser extent transthyretin (also referred to as thyroxine-binding prealbumin) and albumin. The fact that less T3 circulates in complex with plasma proteins means that the ratio of free T4 to T3 is around 4-fold, with typical circulating free hormone levels around 20 picomolar (pM) and 6 pM, respectively. The free fraction is considered biologically active and can enter target tissues.

LOCAL REGULATION OF THYROID HORMONE AVAILABILITY

As outlined, thyroid follicular cells synthesize primarily T4 but also some T3. Critical, however, to the development of certain tissues is the amount of locally available T3, which is the primary driver of the physiologic response to the THs due to its genomic signaling capabilities. The regulation of local cellular ligand availability is mediated by the availability of circulating of THs in conjunction with: 1) cellular transporters that allow for the entry of T4 and T3 into cells, and 2) deiodinases that determine the amount of intracellular T3 made available for genomic and nongenomic signaling (Fig. 67.1).

The importance of specific cell surface TH transporters came to light in 2003 when MCT8 was identified, in cloning experiments performed with *Xenopus* oocytes, as being able to transport T4 and T3 across cell membranes through a channel specific to the iodothyronines.[9] Soon after the identification of the MCT8, its relevance in humans was quickly identified based upon the fact that relevant mutations that impaired its function were discovered in patients with the Allan–Herndon–Dudley syndrome (AHDS), a rare X-linked syndrome leading to a severe intellectual and motor delay syndrome in affected males.[10,11] Indeed, besides the severe clinical syndrome often resulting in early mortality in this syndrome, AHDS patients had long been characterized by the presence of relatively normal thyroid-stimulating hormone (TSH) with a low T4 and high T3. Extensive work on the function of the MCT8 suggests that the syndrome is the result of severe neurologic hypothyroidism mediated by the inability of THs to cross the blood–brain barrier and neurons *in utero*, leading to the clinical syndrome after birth. The peripheral TH abnormalities are at least partially explained by a central resistance to feedback at the level of the hypothalamus and pituitary in the regulation of TSH production, coupled with the requirement of the MCT8 for the movement of T4 out of the thyroid follicular cell via the basolateral membrane into the circulation, leading to enhanced thyroidal T3 production and release. In addition, the consumption of available T4 by the type 1 deiodinase (Dio1; see later) in the liver may also play a role in its low levels and the elevated T3 levels, and there may also be a role for enhanced renal metabolism in AHDS patients.[12] Importantly, if TH analog therapy is used in patients with AHDS, the circulating levels of T3 fall with proper regulation of central TSH production.[13]

While MCT8 is the best-characterized TH transporter, other family members exist, and their cell-specific expression can certainly help to determine cellular TH levels. Currently, many other TH transporters have been identified, including monocarboxlate transporter 10 (MCT10), organic anion transporting polypeptide 1C1 (OATP1C1), and SLC17A4. Interestingly, a mutation in OATP1C1 has been identified in a teenager with neurocognitive and motor deficits. Its further importance as a transporter became apparent in mouse studies, where MCT8 knockout mice were found to have a normal neurologic phenotype likely because of the presence of OATP1C1 that allowed for TH transport into the brain.[13a] Importantly, OATP1C1 does not appear to play a developmental role in TH transport in humans. Significantly, MCT8/OATP1C1 double knockout mice develop severe neurologic hypothyroidism akin to that seen in AHDS.[14] In addition to their role as transporters of T4 and T3 into cells, it is likely that TH transporters also play a role in the efflux of THs from cells, and this in particular may be the role of MCT10. Much work remains to be done in order to elucidate the cell-specific mechanisms of TH transport.

Once TH reaches a particular cell type, the resulting T3 availability for signaling is mediated by the deiodinase family. Also, as reviewed in another chapter, the deiodinases can be classified into activating and deactivating subtypes in context of their ability to produce T3. While Dio1, which is preferentially expressed in liver, can metabolize T4 to either T3 or the inactive rT3, its action is primarily to produce T3. Similarly, the type 2 deiodinase (Dio2) plays a significant role in T3 production in many tissues, including neurons, the cochlea, and skeletal muscle (Fig. 67.1). In contrast, the type 3 deiodinase (Dio3) inactivates T4 to rT3 and T3 to T2 in a variety of tissues, especially developmentally, but is also expressed ectopically in the syndrome of infantile hepatic hemangiomatosis, leading to “consumptive hypothyroidism” and demonstrating its role. Certainly the fine tuning of expression of intracellular deiodinases play a significant role in T3 availability for signaling.[15]

THYROID HORMONE RECEPTORS AND THEIR RESPONSE ELEMENTS

The majority of the actions of the THs are mediated by the interactions of T3 with its cognate nuclear receptors, the thyroid hormone receptor (TR) isoforms (Fig. 67.2). While the bulk of T3 action is mediated by the genomic actions of the TRs, evidence is certainly accumulating that there are fast-acting nongenomic actions of T3 that are mediated by the TRs via their actions in the cytoplasm. Evidence of the nuclear actions of T3 first came into view in the 1960s, when Tata demonstrated the significant action of T3 on RNA synthesis in the liver and the requirement for RNA synthesis for the metabolic effects of T3.[16] Subsequent work by Oppenheimer and Samuels in the 1970s demonstrated specific nuclear binding sites for T3 in rat liver, paving the way for the isolation and cloning of the TRs. Interestingly, the pioneering biochemical work in the 1960s and through the 1980s played little role in the first identification of a functional TH receptor. In 1985, the glucocorticoid receptor was the first nuclear receptor identified, and its sequence seemed analogous to the v-erb-A gene of the avian erythroblastosis virus.[17] Subsequently, the Vennstrom laboratory identified human versions of v-erb-A, termed c-erb-A, which is now known as thyroid receptor α, or *Thra,* in humans.[18] At the same time, the Evans laboratory identified a homologous receptor that is now known as the thyroid receptor β, or *Thrb,* in humans.[19] Both receptors were shown at the time to be nuclear and to bind T3 with high affinity. Importantly, the functional concept of similar receptors engaging with a variety of steroid and THs brought about a new era in physiology and therapeutics that continues through this day based on the ability to develop compounds that acts as antagonists or agonists to these nuclear receptors.

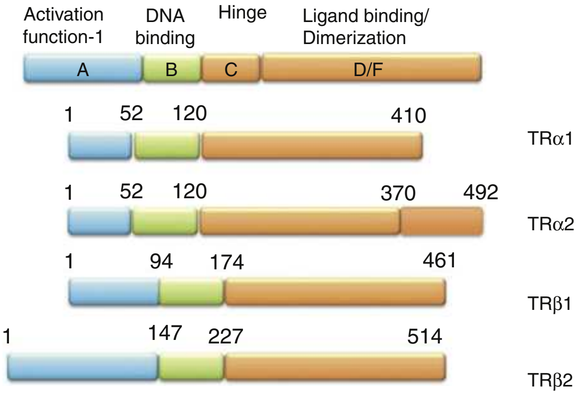

Fig. 67.2 Schematic representation of the thyroid hormone receptor isoforms. Thyroid hormone receptors (TRs) are encoded by the *THRA* and *THRB* genes, which produce multiple isoforms. Depicted are the major isoforms that modulated the actions of triiodothyronine (T3), with exception of TRα2, which does not bind T3 but acts as negative dominant by competing for the thyroid hormone response element with other TRs. TR isoforms share high sequence homology within their functional domains. (From Mendoza A, Hollenberg AN. New insights into thyroid hormone action. *Pharmacol Ther.* 2017;173:135–145.)

Soon after the identification of the original TR isoforms it subsequently became clear that both human *Thra* and *Thrb* were subject to splicing and to the creation of different isoforms (Fig. 67.2). The TRβ gene, located on chromosome 3, produces two major isoforms termed TRβ1 and TRβ2 that differ structurally in their N-termini. In contrast, the TRα gene undergoes splicing in its C-terminus to generate a nonbinding TH receptor isoform termed TRα2, while the principal TH receptor produced from this gene is TRα1. Other isoforms of the TRs have been detected in rodents but are not found or are not functional in humans.[20,21]

Importantly, the tissue of expression more than likely determines the role of the TH receptor isoform, rather than the isoform itself. However, the cell-specific expression of each of the TR isoforms has been difficult to delineate because of their relatively low levels of expression, and the ability of isoform-specific antibodies to identify *in vivo* expression is not strong. Recent genetic approaches to tagging the endogenous alleles in mice has been successful and will yield important information in the future.[22,23] Most of our knowledge of the actions of individual isoforms comes from pioneering mouse genetic studies coupled with the human syndrome of resistance to TH (RTH). TRβ1 is specifically expressed in the liver, where it is a key regulator of cholesterol metabolism and hepatic fat content. Indeed, TRβ1 has long been sought as and continues to be a drug target for the treatment of metabolic diseases, including hypercholesterolemia and nonalcoholic fatty liver disease and its complications. TRβ2 functions specifically in the hypothalamus and the pituitary to regulate the central components of the thyroid axis, including thyrotropin-releasing hormone (TRH) expression in the paraventricular nucleus of the hypothalamus and TSH α and β subunit expression in the pituitary (Fig. 67.3). Interestingly, the exact mechanism by which TRβ2 regulates TRH remains unclear. It is presumed that TRβ2 is expressed in the same neurons as TRH, but because of the lack of reagents available for detecting cell-specific TRβ2, this remains unclear and is an area of important investigation. In addition to its role centrally, TRβ2 plays a key role in the retina, where it controls the proper differentiation of rods and cones to allow for color vision. In contrast to their separate roles, TRβ1 and TRβ2

appear to collaborate in the regulation of hearing, based on their function in the cochlea.[24] TRα1, while present in the liver and pituitary, plays little role in isolation in these tissues. Its major roles include actions in the atrium and ventricle of the heart, as well as in bone, where its expression in a variety of cell types in that tissue is likely to be more than 10-fold more than that of the TRβ isoform.[25] In addition, TRα1 has principal actions in the gastrointestinal tract, where it plays a strong role in function and cell renewal. Additionally, TRα1 is important in the regulation of many actions of THs in the brain, but again, cell-specific actions are limited by available tools. While TRα2 has always been viewed as a potential dominant inhibitor of TRα1, its role *in vivo* does not appear to be paramount in determining cell-specific TH actions. Taken together, it is clear that each of the isoforms have cell-specific functions, likely based on their ratio of expression. However, it remains to be determined in future work whether the isoforms' structural differences delineate a unique genomic response. This would ideally require experiments where TRβ1 would replace TRα1 in a particular target tissue. In experiments performed in cell culture where TRβ1 and TRα1 were expressed at a similar level, there was evidence of isoform specificity in terms of target activation.[26]

As outlined, the TRβ and TRα isoforms are distinct at the nucleic acid and amino acid levels but share a high degree of structural homology that is also shared with other members of the nuclear receptor superfamily. The TRs all possess both a similar DNA-binding domain in the central region of the protein, followed by a ligand-binding domain that is specific for T3 at nM concentrations (with TRα1 having a slight degree of enhanced sensitivity for T3) and overlaps with the activating function 2 domain. What differentiates the TR isoforms are unique N-terminal domains (also referred to as activating function 1 [AF-1] domains) that are relatively unstructured but may allow for differential DNA binding and also possess independent transcriptional properties. The DNA-binding domains of the TR isoforms consist of two zinc finger protein domains that mediate contact with DNA and allow for receptor binding. The specificity of TR binding to target DNA elements is encoded for by the P-box in the first zinc finger. The importance of the P-box is highlighted by experimental mutations in mouse models that have allowed investigators to interrogate the role of the TR in the absence of its ability to bind DNA.[27] The second zinc finger, in conjunction with the C-terminal extension (or hinge region), also plays a critical role in DNA response element recognition of the TR isoforms and in their ability to heterodimerize with the retinoid X receptor (RXR) isoforms, their preferred partners when bound to DNA response elements. Importantly, this interaction with RXR in all cases has RXR bound 5', or upstream, to the TR. This interaction via the DNA-binding domain and C-terminal extension and hinge region with the TR and RXR, confirmed in structural studies, likely explains the preference of the RXR/TR heterodimer for response elements that contain two classic nuclear receptor half-sites (AGGTCA) spaced by four nucleotides (Fig. 67.4). This is in contrast to other nuclear receptor heterodimer pairs such as the vitamin D receptor with RXR and the retinoic acid receptor isoforms with RXR, which prefer elements that have spacings of three and five base pairs, respectively.[28]

The majority of TR isoform binding is likely as a heterodimer with RXR, but it remains possible that the TR can also function to bind DNA as a homodimer, or even as a monomer. To exerts its actions, the TR must engage T3 via its ligand-binding domain (LBD). Structural studies of the TR LBD demonstrate that it, like other nuclear receptors, contains a ligand-binding pocket that is surrounded by 12 alpha helices[29] (Fig. 67.5). That it exerts functions both in the presence and absence of T3, helix 12 (H12) demonstrates an ability to be in an open position in the absence of ligand. When T3 moves into the ligand-biding pocket, H12 shifts and closes over the pocket.[30] This movement of H12 creates two distinct grooves to allow for separate groups of TR-interacting proteins to engage the receptor, either in the presence of or absence of T3. Most likely, in the presence of low levels of T3, the unliganded structure is preferred, while in the presence of excess ligand the liganded structure is preferred (Fig. 67.5). The importance of a variety of these helices in forming the ligand binding pocket for T3 is shown by the many mutations found RTH syndrome, where mutations in the LBD usually lead to a reduced or absent ability to bind T3.[31]

Importantly, structural and biochemical studies have determined the nature of the RXR/TR heterodimer and its ability to engage with target response elements *in vitro* and in cell culture models. Indeed, these techniques identified a variety of T3 response elements such as the DR4 element described previously, as well as palindromic and inverted palindromic arrangements of the AGGTCA half-site. However, identification of the true response elements for the TR *in vivo* was not possible until the development of *in vivo* chromatin immunoprecipitation, which allows for the identification of DNA sequences that engage the TR directly. Experiments performed in mouse liver using an overexpressed TRβ1 isoform that can be biotinylated *in vivo,* and thus precipitated by streptavidin, demonstrated thousands of binding sites for the TR, with many of the sites located at great distances from regulated genes or within introns. Classically regulated T3 targets, such as the Dio1 gene, was shown to have TR binding sites in its first intron, while the spot 14 and fatty acid synthase genes had more traditional sites within 10 kB of their transcription start sites. Importantly, using motif enrichment tools, the most common binding site seen was the DR+4 element, and there was good overlap with previously known RXR binding sites, demonstrating the action of the heterodimer *in vivo*. However, not all TR binding sites were also occupied by RXR, raising the possibility that the TR homodimer and monomer could also play a role in TH action. While DR+4 sites were associated with genes induced or positively regulated by T3, there were fewer binding sites associated with genes negatively regulated by T3.[32] Similar results were seen in experiments in mouse liver utilizing an antibody against the TR itself, again with the DR+4 motif predominating.[33] Interestingly, in both of these studies a percentage of TR-binding sites were enhanced in the presence of T3, suggesting that the traditional view of the TR being engaged on DNA response elements irrespective of the concentration of ligand is not correct for every response element. The significance of the DR+4 motif in TR binding has been further supported by cell culture studies using tagged TRs that could either be biotinylated or immunoprecipitated. Finally, a recent mouse model utilized a strategy whereby the endogenous TRβ1 allele was tagged at its N-terminus by hemagglutinin (HA) sequences and would thus be expressed with a tag that could be immunoprecipitated by an antibody directed against HA. In liver chromatin, this model confirmed the importance of the DR+4 element as the primary TRβ1 binding site but also demonstrated a role for the DR+4 binding site in mediating negative regulation or the downregulation of genes in the presence of T3. Interestingly, this novel model also suggested that T3-mediated recruitment of the receptor did play a significant role across the genome.[23] Thus, these *in vivo* unbiased approaches to examining TR binding to DNA are beginning to articulate a picture whereby the DR+4 element is paramount for TR binding, especially in liver. Further work will be required to demonstrate that the binding sites identified (especially in the context of negative regulation) actually mediate regulation of the gene in closest proximity. Indeed, it remains possible that distinctly different binding sites that are less frequently seen and are at great distances from target genes may play critical roles in regulation.

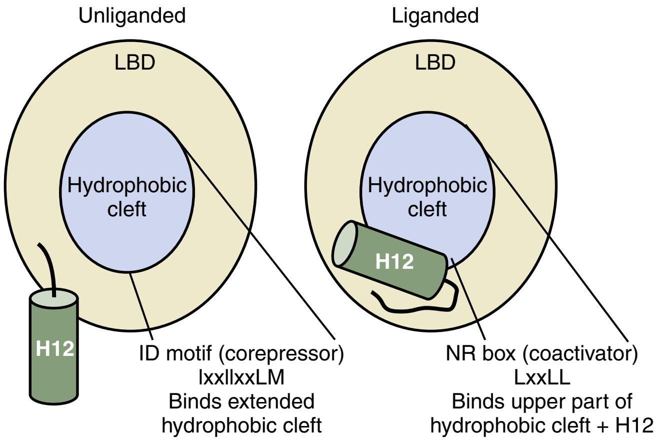

Fig. 67.5 Helix 12 position and coregulator binding. Thyroid hormone receptor TR C-terminal helix 12 is displaced away from the hydrophobic cleft without bound hormone, exposing a large hydrophobic cleft, which serves as an interaction site for α-helical motifs from corepressors (IDs). With hormone, H12 packs over the lower part of the corepressor binding surface, blocking corepressor binding and creating a new binding site for coactivator NR boxes (LxxLL). *LBD,* Ligand-binding domain.

Thyroid Hormone Receptor Coregulatory Proteins

Beginning in the 1990s it became clear that the TR recruited activity that was dependent upon the presence or absence of ligand. In these

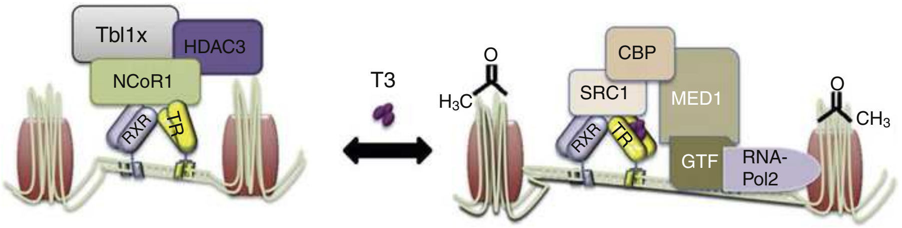

Fig. 67.6 CoRepressors and CoActivators are recruited to the TR based on the presence of ligand. In the absence or in the presence of limiting amounts of T3 the TR recruits the nuclear corepressors (ie NCoR1) as part of a multiprotein complex to repress transcription. In the presence of T3 the corepressor complex is dismissed and coactivators including SRC1 are recruited to activate trasncription. Coregulators, corepressors, and coactivators harbor nuclear receptor–interacting domains. NCoR1 and SMRT harbor three nuclear receptor interacting domains; N3 and N2 interact preferentially with unliganded thyroid hormone receptor (TR), whereas steroid receptor coactivator (SRC) harbors an RID region that interacts with the TR upon adoption of the liganded conformation. (From Mendoza A, Hollenberg AN. New insights into thyroid hormone action. *Pharmacol Ther*. 2017;173:135–145.)

studies the TR-LBD was fused to a heterologous DNA-binding domain (in this case yeast Gal4), and its function could be altered by the presence of a full-length TR that would compete for the activity allowed for by the Gal4-TR hybrid.[34] Central to these experiments was the long-held observation that, in cellular transcriptional assays on artificial DNA-binding elements, the unliganded TR was a potent repressor of gene expression for positive target genes, while it activated the expression of the regulatory elements of negatively regulated target genes. With the addition of T3, the TR then activated positively regulated genes and repressed negatively regulated genes, demonstrating that the TR possessed repressing and activating functions, depending upon the presence of ligand. The importance of the function of the unliganded TR was further highlighted by genetic studies demonstrating that mice could survive the deletion of all TRs, while mice that lacked TH at birth that was not replaced could not survive.[35]

To identify proteins that could mediate differential functions of nuclear receptors and the TR based on the presence or absence of ligand, pivotal experiments were performed initially using an immobilized estrogen receptor LBD to screen radiolabeled cellular lysates for target-interacting proteins or yeast-two hybrid assays using the LBD of a nuclear receptor as bait to identify interacting proteins either in the presence or absence of ligand. The results of these experiments and many others that followed was the identification of groups of proteins that could interact with the TR based on ligand availability, and as a field include hundreds of proteins. Strikingly, as will be outlined later, a central quality of the majority of these interacting proteins was an ability to enzymatically alter histone acetylation or methylation, implying that the TR functions as an epigenetic switch to modify chromatin in the presence or absence of its ligand.

Two general classes of proteins that interact with the TR are fundamental to its actions and are termed corepressors and coactivators (Fig. 67.6).[36,37] As their names suggest, they offer distinct regulatory functions based on their recruitment. Importantly, the structure of the TR-LBD, with the location of H12, predicts how they may be differentially recruited. Indeed, coactivators, which include members of the steroid receptor coactivator (SRC-1, 2, and 3) family, CREB-binding protein (CBP)/p300 and coactivator-associated arginine methyltransferase 1 (CARM1), and protein arginine N-methyl transferase 1 (PRMT1) all contain motifs termed nuclear receptor–interacting domains, which are specified by leucine-rich motifs (LxxLL) that dock in a groove created by a closed H12 as T3 binds.[38] In contrast, the corepressors heralded by nuclear receptor corepressor 1 (NCoR1) and the silencing mediator of the retinoic acid and TH receptor (SMRT or NCoR2) possess in their C-terminus isoleucine-rich domains (LxxH/IxxII), also termed CoRNR boxes, which bind to the groove in the unliganded TR created by the open position of H12.[39,40] It is likely that, in the presence of limiting amounts of T3 or in the hypothyroid state, the majority of TRs exist in the unliganded state, and as T3 concentration increases, the liganded-conformation is favored, corepressors are dismissed, and coactivators are recruited. However, mouse genetic experiments and human genome-wide association study (GWAS) data suggest that the amount of specific coregulator present dictates the ability of the TR to be activated or repressed. For example, in humans with excess NCoR1, T4 levels must be higher to achieve normal TSH levels. Similarly, mice that lack functional NCoR1 have lower TH levels with a normal TSH. Taken together, these data suggest that the corepressor/coactiviator ratio *in vivo* regulates sensitivity to TH.[41,42]

As discussed, the principal coactivators of the TR include members of the SRC family, CBP/P300, the methyltransferases, and also members of the Mediator complex. There are likely others also that play a role, depending on the target gene and cell type where T3-dependent regulation is occurring. The SRC family is recruited to the T3-bound RXR/TR heterodimer via their nuclear receptor–interacting domains, which demonstrate specificity to particular nuclear receptors. It is likely that CBP/p300 and other coactivators are scaffolded on the principal SRC–TR interaction, and thus play an essential role. The Mediator complex appears to link the activated TR complex to RNA polymerase. It has also been suggested in biochemical assays that SRC-1 makes contact with TR isoforms via the N-terminal or AF-1 domain, which could play a role in T3-mediated negative regulation. Genetic analysis of coactivator function in mice has demonstrated a critical role for SRC-1 in T3 action both in the liver and centrally, where these mice display a phenotype of resistance to TH, implying that SRC-1 is required for determining the set point of the hypothalamic-pituitary-thyroid (HPT) axis.[43] When deleted in conjunction with individual TR isoforms, SRC-1 has also been shown to play a role in growth and body weight that could be T3-dependent. However, SRC-1 may not play a role in the regulation of heart rate by T3. In contrast to SRC-1, murine knockout studies of SRC-2 and SRC-3 demonstrate no specific defect in T3 action, though they have numerous other metabolic phenotypes. Much work remains to be done to ascertain the specific coactivators that allow for the cell-specific actions of TR isoforms.[36]

The principal TR corepressors NCoR1 and SMRT also form a multiprotein complex that mediates histone deacetylation and transcriptional repression. The large, 270-kD proteins are paralogs and share homology in terms of their domain structure but have specificity in terms of their ability to interact with nuclear receptors, including the TR. The N-terminal regions of NCoR1 and SMRT contain repression domains that recruit proteins such as G protein pathway suppressor (GPS2) and transducin β-like 1 (TBL1 or TBL1X) and its homolog, TBL-related 1 (TBLR1or TBL1XR1), which all together form the core repression complex, together with HDAC3, which is recruited and activated by a specific domain (deacetylase activation domain [DAD]) present in both NCoR1 and SMRT. Mice that lack a functional DAD domain can no longer mediate deacetylation but still have repressive properties, indicating that NCoR1 and SMRT have activity independent of their ability to recruit and activate HDAC3. The C-termini of NCoR1 and SMRT contain three nuclear receptor–interacting domains that mediate interactions with nuclear receptors. Early biochemical studies suggested a preference of NCoR1 for the TR, but testing of this was hampered *in vivo* by the fact that global deletion of NCoR1 or SMRT is embryonic-lethal in the mouse. To get around this lethality, a mouse model was developed that created a hypomorphic NCoR1 allele, termed NCoRΔID, that encoded the full NCoR1 protein except for the two interacting domains that are required for interactions with the TR.[44] Using this targeted allele, tissue-specific or global models could be built that would live and express an NCoR1 protein that was nonfunctional in terms of TR action. In each model developed where NCoRΔID was expressed in lieu of NCoR1, mice displayed evidence of increased sensitivity to T3. For example, in mice where NCoRΔID was expressed in all tissues, both T4 and T3 levels were significantly low in the sitting of normal TSH, yet energy expenditure was increased, growth was normal, and T3-mediated gene expression was normal, all of which is consistent with increased sensitivity to T3. Further proof of this concept was provided by mice with the PV mutation causing RTH present in their Tβ or TRα alleles. When crossed with NCoRΔID mice, the syndrome of RTH was corrected in both models, again consistent with NCoR1 mediating sensitivity to T3.[45] Similarly, in NCoRΔID mice that lacked SRC-1, increased sensitivity to T3 was reversed, confirming the notion that the balance between available corepressors and coactivators determines sensitivity to T3.[46] Further support for this hypothesis comes from the identification of a variety of NCoR1 splice variants *in vivo* that, in turn, alter hormone sensitivity.[47] The importance of this observation likely carries

TABLE 67.1 Thyroid Hormone Action Classification

Action Type	Category	Description
Type 1	TR-dependent signaling of TH with direct binding to DNA	Canonical TH signaling, TR binds directly to consensus TRE
Type 2	TR-dependent signaling of TH with indirect binding to DNA	TR indirectly modifies gene expression by chromatin remodeling, possibly tethered to DNA by other transcription factors
Type 3	TR-dependent signaling of TH without DNA binding	Cytoplasmic TR can activate kinases and promote membrane signal transduction pathways
Type 4	TR-independent TH signaling	TH interaction with membrane receptors, including integrins and actin polymerization

TR, Thyroid hormone receptor; *TH*, thyroid hormone; *TRE*, thyroid hormone receptor response element.
From Flamant F, Cheng SY, Hollenberg AN, et al. Thyroid hormone signaling pathways: time for a more precise nomenclature. *Endocrinology*. 2017;158:2052–2057.

through to humans, where GWAS and quantitative trait locus studies demonstrate that increased free T4 levels are associated with increased NCoR1 in order to overcome the decreased sensitivity due to higher levels of NCoR1.[42] Interestingly, human mutations in TBLX1 have also been described, and in these patients TH levels are low and the TSH is normal. Currently, they are classified as having central hypothyroidism, but it remains possible that, if the corepressor complex is dysfunctional, they would in fact have increased sensitivity to TH.[48] The specificity of NCoR1 for the TR has been further confirmed in mouse models that either delete SMRT action in the liver or globally in adulthood to get around the embryonic lethality of early SMRT deletion. In both of these models, SMRT had no effect on the regulation of T3 target genes or in the systemic regulation of the HPT axis.[49,50]

POSITIVE AND NEGATIVE GENE REGULATION BY THYROID HORMONE

The majority of TH's actions are mediated by its genomic regulation via the TR isoforms and their ability to recruit coregulators to modify the histone environment to stimulate or repress target genes, referred to as type 1 action. While each of the players are now known, it is likely that multiple mechanisms regulate target genes. Indeed, the regulation of TH action by the TR has been classified into three distinct subtypes: 1) direct regulation of target genes by bound TR; 2) regulation of gene expression by tethered TR, i.e., via another transcription factor; and 3) regulation that is independent of TR recruitment or due to nongenomic mechanisms (Table 67.1).[51]. A number of recent studies have addressed positive regulation using genetic mouse models and genome-wide chromatin assays to clarify the mechanism by which T3 induces gene expression, particularly in the liver, where hundreds of genes are both upregulated and downregulated by T3.[23,52,53] To date, most positive regulation by the TR is explained via its direct binding to genomic response elements (Fig. 67.1). TR action occurs at many regulated genes, whereby, in the absence of T3, there is decreased histone acetylation (H3K27 and H3K9) in regions in proximity to the regulated gene that correspond to a TR binding site. The acetylation status of these sites is controlled by the recruitment of NCoR1 and HDAC3, and the presence of T3 leads to hyperacetylation via the accrual of coactivators such as SRC-1 and CBP, leading to enhanced histone acetylation. Examples of such classically regulated targets include spot14, fatty acid synthase, and malic enzyme. Interestingly, many direct targets of the TR are repressed independently of NCoR1, such as the Dio1 or cyp17a1 genes, suggesting that either repression is mediated by a separate corepressor, or repression of these targets is mediated by a lack of TR binding that only occurs when T3 is present, which then leads to the recruitment of coactivators that mediate histone acetylation and gene expression. Importantly, chromatin immunoprecipitation analysis of histone acetylation discloses many areas of the genome that are acetylated in response to T3 but that are not near a TR binding site. It remains possible that remote TR binding sites act from a great distance to regulate these areas of histone acetylation and potentially target genes.

KEY POINTS

- The structure of the thyroid hormone receptor isoforms ligand-binding domain changes secondary to the amount of ligand present, which determines the type of coregulator complex recruited and confers tissue-level sensitivity.

While the mechanisms underlying positive regulation have become clearer with genome-wide techniques, the mechanisms underlying negative regulation by TH remain in question. Understandably, many studies have focused on how the TRβ isoform regulates TRH and TSH subunit gene expression, given the importance of this in determining the set point of the thyroid axis. The regulation of the central axis is known to be dependent on TRβ2 via its ability to bind to DNA, as mouse models that either lack the isoform or express a TRβ isoform that cannot bind DNA have evidence of central resistance to TH, with elevated TRH mRNA expression and increased TSH subunit gene expression. Furthermore, the coactivator SRC-1 also appears to play a role in the regulation of the central axis, as its deletion leads to central resistance to TH. In contrast, expression of NCoRΔID in the absence of SRC-1 reestablishes the proper set point of the axis, implying that TRH and TSH subunit gene expression is mediated by the TRβ2 isoform via its interactions with NCoR1 and SRC-1. However, studies to date have not defined this at the cellular level in terms of demonstrating intact DNA-binding sites for the TR in the hypothalamus or pituitary.

Early experiments using cotransfection assays in heterologous cell lines identified TR binding sites in regions close to the transcriptional start site of the TRH and TSHβ genes. Indeed, site 4 in the TRH promoter recruits the RXR/TR heterodimer, while a strong monomeric TR binding site exists just downstream of the transcriptional start site of the TSHβ gene. However, the importance of these sites *in vivo* has been difficult to test because of the difficulty of isolating hypothalamic and pituitary cell types for genome-wide analyses utilizing chromatin immunoprecipitation and other such techniques. Recent work, therefore, has focused on the liver, which is more accessible to *in vivo* approaches, to define the mechanism.

As outlined earlier, hundreds of genes are regulated negatively by T3 in the liver and follow the classic example of gene activation in hypothyroidism and then repression in hyperthyroidism. Deletion of TRβ isoforms in hepatocytes alone demonstrates its requirement for negative regulation in the vast majority of cases. Analysis of the requirement of TRβ binding in the vicinity of negatively regulated targets suggests that its binding is important for a significant number of genes, but not all. Furthermore, motif enrichment analysis has suggested the presence of either a DR+0 motif, or more recently a DR+4 motif, that would recruit the TR.[23,32] While direct TR binding is likely important, there is also clearly a role for negative regulation via independent actions of the TR in context of inducing another pathway (i.e., microRNA regulation) or interacting with another transcription factor.[54] The roles of the corepressors and coactivators are less clear, as other SRC isoforms appear to compensate for the loss of SRC-1 when it is ablated, as negative regulation is preserved in the liver of SRC-1 knockout mice. When NCoR1 is disrupted in the liver, negative regulation is also preserved, and SMRT appears to play little compensatory role. Still, recent work that demonstrates DR+4 TRβ binding sites in enhancers near negatively regulated genes suggests that it is the ratio of coactivators to corepressors recruited that determines target gene regulation, such that, in the hypothyroid state, there is enhanced coactivator recruitment leading to histone acetylation and enhanced gene expression, while the presence of T3 leads to enhanced corepressor recruitment and gene repression. Further *in vivo* work will be required to clarify the exact mechanisms of negative regulation.

Thyroid Hormone Receptor Posttranslational Modifications

KEY POINTS

- Most positive regulation by the thyroid hormone receptor (TR) is explained via its direct binding to genomic response elements. TR action occurs at many regulated genes, whereby, in the absence of triidothyronine (T3), there is decreased histone acetylation (H3K27 and H3K9) in proximity to the regulated gene. The acetylation status of these sites is controlled by the recruitment of NCoR1 and HDAC3, and the presence of T3 leads to hyperacetylation via the accrual of coactivators such as SRC-1 and CBP, leading to enhanced histone acetylation.

While the TR isoforms are strongly influenced by ligand both in terms of coregulator recruitment and DNA binding, it is also clear that other signaling pathways impact their function. The TRα isoform is known to possess a protein kinase A site within its DNA-binding domain that may interact with its ability to bind to DNA, though this has not been shown *in vivo*. Additionally, TRβ can be phosphorylated, but the significance is not known.[55] Most interestingly, both TR isoforms can be sumoylated, with TRα having two sites and TRβ three.[56] The mutation of sumoylation sites on either isoform impairs their ability to mediate ligand-dependent gene activation or repression, potentially through aberrant or diminished coregulator recruitment. Furthermore, active introduction of TR isoform sumoylation mutants interfered with the normal differentiation of preadipocytes into adipocytes. Importantly, the sumoylation sites present on TRβ appear to govern distinct pathways involved in adipogenesis, including Wnt signaling and nuclear receptor signaling via coregulator recruitment.[57]

NONGENOMIC THYROID HORMONE ACTION

While the majority of TH action is mediated by T3 engaging its cognate receptor in the nucleus, there have been significant advances in understanding rapid or nongenomic actions of T3 via a cytoplasmic TR isoform (Table 67.1). However, some actions of T3 are felt to occur too quickly to be explained by a genomic process. Indeed, *in vitro* and *in vivo*, when present in the cytoplasm, the unliganded TRβ can interact with p85, the regulatory subunit of PI3 kinase. This interaction, mediated by one of the zinc fingers in the DNA-binding domain, is blocked by T3, and PI3 kinase signaling is induced. If the site necessary for PI3 kinase interaction is mutated *in vivo* in a mouse knockin model, normal nuclear TRβ signaling is preserved in terms of the HPT axis and induction liver target genes. However, synaptic strength and plasticity in hippocampal neurons studied in slices was significantly less in the mutant mice, implying that PI3 kinase activation via the TRβ isoform is critical.[58] Further support for rapid nongenomic effects of the TR isoforms comes from more recent experiments, where *in vivo* mouse models were developed that possessed mutations in the first zinc finger of both the TRα and TRβ isoforms that prevented DNA binding, and T3 signaling was compared with wild-type controls. Strikingly, TRβ mutant mice could still selectively regulate glucose and triglyceride lowering, and additionally temperature elevation, while TRα mutant mice could still regulate heart rate in response to *in vivo* circulating T3 levels. Importantly, the effects in the TRβ DNA-binding mutant mice on glucose, triglycerides, and temperature were blocked in the mouse model where T3-mediated PI3 kinase activation was inhibited. Taken together, these data suggest that it is likely that the TR isoforms can have noncanonical effects (so called type 3 signaling) that impact physiology and are likely regulated through the activation of PI3 kinase.[58]

THYROID HORMONE TISSUE-SPECIFIC ACTIONS

Thyroid Hormone Receptor Isoform–Specific Expression

As described previously, TRs are expressed in essentially all tissues, although well-defined tissues, such as liver, heart, and brain, express higher levels of TRs than other organs[21,59] (Fig. 67.3). The estimates of TR isoform content across tissues have varied depending on the tool that is used to detect TR, which have included T3 binding, TR isoform mRNA levels, western blot with antibody to native TR protein, or introduction of specific immunogenic “tags” into the TR protein for detection by a standard antibody that has a high affinity for that tag. There are limitations to all of the approaches used, which result in wide variations in estimates of TR isoform content, especially those relying on mRNA measurement rather than protein. The affinity and specificity of antibodies for TR isoforms also varies, and there are additional differences in tissue TR content based on the species that is studied. A “knockin” strategy involves introducing a standard HA tag sequence into the *Thra* and *Thrb* genes in mice and then measuring protein content in various tissues with a high-affinity antibody that recognizes the HA tag.[22] TRα was the predominant form in all tissue, except liver, where TRβ was predominant. In metabolically-responsive tissues, including fat and muscle, TRα protein levels were 10 times higher than those of TRβ protein. In the brain, there were low levels of TRα and TRβ, but high levels of TRα2, which does not bind T3. TRβ2 was very high in the pituitary, as has been previously reported, but an interesting sex difference was seen, with TRβ2 content greater in females than males, and females had lower serum TSH and *Tshb* mRNA. TR isoform expression can also vary within a tissue. The heart has predominantly TRα in the atria, mediating the chronotropic actions of TH, and the ventricle contains more TRβ. The phenotypes of individuals with RTH beta and alpha have largely been validated as being associated with TR isoform–specific functions, which have also been identified in mouse, *Xenopus,* and zebrafish models.[60] A further variation is TR intracellular distribution. Although TR resides predominantly in the nucleus, there is rapid shuttling between the cytoplasm and nucleus that varies by specific TR isoform.[61]

Growth

TH is necessary for proper growth and development of the fetus, as well as for normal child development, and exerts widespread influences on multiple aspects of metabolism and organ function in adults. TH regulation of gene expression in development is complex, and several important underlying principles have been identified.[21,62] First, developmental defects that arise in hypothyroid mothers are not reversed by later hormone replacement, whereas adults with TH imbalances exhibit metabolic disturbances that in most cases can be reversed by restoring TH to correct levels. TH triggers key developmental events in defined temporal windows, with abnormalities seen with both deficient and excess TH, especially as has been shown in sensory development of the inner ear and retina.[63] These developmental windows are regulated by specific expression of TR isoforms and the Dio2 enzyme, which activates T4 to T3, and the Dio3 enzyme, which converts T4 to the inactive rT3. TH-regulated genes important for organ function in the adult, such as those involved in metabolic regulation and brain function, remain sensitive to alterations in hormone levels, and gene expression is linked to thyroid status.

Gene expression patterns reveals that some genes are induced in multiple tissues, whereas other target genes are regulated in a manner that is highly tissue- and gene-specific. Another additional level of regulation is TH action on expression of microRNAs, an emerging area of TH regulation.[64] Thus, TH is a primary regulator of some genes, but the hormone must cooperate with other factors to induce expression of other genes. An example is TH metabolic regulation, which involves "crosstalk" with other metabolic regulators, including peroxisome proliferator-activated receptor (PPAR)α and PPARγ, as well as PPARγ coactivator 1-α (PGC-1α).[65,66]

Specific effects of TH will be discussed, arranged by the tissue or site of action.

Stem Cell Proliferation

In most tissues, TH stimulates stem cell proliferation as well as differentiation, in contrast to morphogens, like retinoic acid, that predominantly promote differentiation.[67] Direct TH stimulation of stem cell proliferation, predominantly mediated by TRα, includes stem cells in the intestine, skeletal muscle, pancreatic islets, heart, liver, adipose tissue, bone, and neurons[67,68] (Table 67.2). In many tissues, such as skeletal muscle and pancreatic islet cells, the stimulation of stem cells requires TR, but is also regulated by local production of T3, by actions of Dio2 and Dio3.[69] Stimulation of stem cell proliferation is important in development, but also to mediate regeneration after injury, as has been shown in skeletal muscle, cardiac muscle, and brain.[70] These findings have led to an interest in TH treatment in a variety of conditions to promote regeneration after injury, such as traumatic brain injury, stroke, myocardial infarction, and muscle injury.

KEY POINTS

- Stimulation of stem cell proliferation is important in development, but also to mediate regeneration after injury, as has been shown in skeletal muscle, cardiac muscle, and brain.

Thyroid Hormone and Somatic Growth

TH deficiency in both the mother and fetus results in reduced somatic growth. Normal maternal thyroid status is sufficient to compensate for fetal thyroid deficiency in congenital hypothyroidism, with maternal TH crossing the placenta from high to low levels in the fetus. Combined maternal and fetal hypothyroidism, as seen in profound iodine deficiency, results in irreversible somatic growth deficit. Hypothyroidism in children is associated with reduced height. TH directly stimulates production of growth hormone in some species, including mice and rats. In children with deficiency of both growth hormone and TH, treatment with both hormones works to restore normal growth.

Brain

TH is required for normal brain development, initially from transport of maternal TH across the placenta and then from TH produced by the human fetus, at around 13 weeks, when the thyroid gland develops.[71] Maternal TH can compensate for defective fetal thyroid gland development in the condition referred to as congenital hypothyroidism. The infant, however, must be identified by screening at birth and started promptly on TH replacement to support normal brain development. The combination of maternal and fetal TH deficiency, as is seen with profound iodine deficiency during development, is associated with profound and irreversible abnormalities of brain and nervous system development.

TRα1 is the predominant TR isoform in most of the brain, although TRβ2 is the TR isoform expressed in the pituitary and hypothalamus[21,22] (Fig. 67.3). TH is important for neural stem cell proliferation and expression of both neurons and glial cells.[72,73] TH promotes neurogenesis and oligodendrocyte differentiation and maturation.[74-76] A number of TH-stimulated gene targets have been identified in the cortex, hippocampus, and cerebellum. TH induction of a number of genes in the brain is antagonized by the expression of chicken ovalbumin upstream transcription factor 1 (COUPTF1), which has a developmental pattern of expression and blunts the expression of neural differentiation in key developmental windows.[77] TH induction of neural proliferation is not only important developmentally, but has also been shown to play a role in recovery after brain injury. TH treatment reduces hypoxia-induced damage and promotes recovery.[78] TH treatment within a few hours of traumatic brain injury in rodent models significantly reduces the extent of injury and promotes recovery.

Genes have been identified in rodent models that are TH-responsive and important in neurogenesis, including T-box brain transcription factor 1 (*Tbr1*), *Sox2*, and neurogenin1.[79,80] A TH gene target in the hippocampus, and area important for memory and emotion, is calcium calmodulin ATPase IV (CamKIV). CamKIV is upregulated by T3, but stimulation is inhibited by COUPTF1.[81]

Oligodendrocyte differentiation is promoted by TH, and a number of gene targets have been identified. Myelination is promoted by the TH-stimulated, and TH analog-induced expression of myelin basic protein has been reported.[82] Another TH gene target is glial fibrillary acidic protein (GFAP), which is expressed in astrocytes. GFAPs form the intermediate filament and play an important role in neural support. TH and TH analog promotion of myelination have been used to promote myelination in models of demyelinating illness, such as multiple sclerosis. In addition to stimulating myelination, TH and thyromimetics have been shown to act to inhibit myelin and axonal degeneration and oligodendrocyte loss in models of autoimmune encephalitis.[83]

Mouse models with THRA1 mutations have various defects, depending on the mutation, but most have shown some defects in brain development, neurological impairment, and behavioral abnormalities.[84] Defects include those of neuronal and glial cell lines.

TH regulates brain development, and hypothyroidism results in intellectual disability and multiple neurologic defects.[59] Slow mentation and other central nervous system disturbances characterize

TABLE 67.2 **Thyroid Hormone Receptors and Proliferation/Differentiation**

Cell Type	Proliferation	Primary Receptor	Genes/Pathways	Response Modulated
Hepatocyte	Increased	TRβ	Cyclin D1	Liver hyperplasia, liver regeneration, regression of neoplastic nodules
Pancreatic β cells	Increased	TRα, TRβ	Cyclin D1/CDK/Rb/E2F PI3K/Akt	Cell proliferation and survival during pancreatic development
Intestinal epithelial cells	Increased	TRα	Wnt/β-catenin Notch, BMP	Intestinal maturation and renewal
Cardiomyocytes	Increased	TRα	MHCα, ANF, SERCA2, β-1 adrenergic receptors, K+ channels PI3K/AKT	Contractility, heart rate, cardiac hypertrophy, cardiomyocyte maturation
Skeletal muscle cells	Increased	TRα	MyoD and contractile genes	Muscle contraction, repair in response to injury

hypothyroidism. In hyperthyroidism, there can be episodes of anxiety and even psychosis. CamKIV, a TH-responsive gene expressed in the hippocampus, is important in learning and memory, and reduced expression may be responsible for some of the cognitive deficit seen in patients with hypothyroidism.

KEY POINTS

- Thyroid hormone (TH) is important for neural stem cell proliferation and expression of both neurons and glial cells. TH promotes neurogenesis and oligodendrocyte differentiation and maturation. TH and TH analog promotion of myelination have been used to promote myelination in models of demyelinating illness and recovery from brain injury.

Heart and Blood Vessels

THs have multiple effects on the cardiovascular system.[85] One action is to increase cardiac output via an increase in cardiac contractility and heart rate. TH regulates genes involved in cardiac contractility; there is induction of the sarcoplasmic reticulum Ca^{2+} ATPase 2, involved in calcium reuptake during the diastolic phase, and α myosin heavy chain (MHC), a fast ATPase required for heart contractility that is expressed in adult heart. Conversely, TH inhibits expression of βMHC, a slow ATPase expressed in embryonic heart and upregulated in stress conditions. Excess TH, in contrast, is associated with atrial arrhythmias, as well as development of high-output heart failure. TH and its analogs have been used to increase cardiac output in heart failure patients and after coronary artery revascularization, with modest improvement.

Skeletal Muscle

THs promote muscle catabolism and increase skeletal muscle energy expenditure in adults.[15] TH also induces the insulin-sensitive glucose transporter in muscle and promotes fat burning. These effects may help to sensitize muscle to insulin response. Accordingly, human Dio2 gene polymorphisms are correlated with insulin resistance in human populations, although this finding remains controversial.[86] TH has a specific role in promoting proliferation of satellite cells and skeletal muscle stem cells, during development and during regeneration following injury.[70] TH activation, T4 to T3 conversion by Dio2,[87] and the presence of the TRα are required for normal development and response to injury.

Skeletal System

TH is required for normal bone growth and maturation.[88] Juvenile hypothyroidism causes delayed bone formation and short stature, whereas thyrotoxicosis leads to increased growth and advanced skeletal development. In adults, however, TH excess promotes bone resorption. TH excess can lead to osteoporosis, especially in postmenopausal women.

Small Intestine

TH is required for normal maturation of the small intestine. A prominent phenotype of mice with TRα deletions and mutations is abnormal development of the small intestine and malabsorption. TRα1 is required for proliferation of intestinal epithelial progenitor cells via induction of the β-catenin protooncogene and underlies TH action.[89]

Metabolic Regulation and Actions in Liver

One of the most important effects of TH involves metabolic regulation, including changes in basal metabolic rate (BMR) in multiple tissues (Table 67.3).[66] THs stimulate oxygen consumption (indicative of enhanced metabolism) in multiple locations, including skeletal muscle, liver, kidney, and intestine. TH potentiates adrenergic signaling.[90] Increases in BMR are probably partly related to increased mitochondrial activity and number, but details of how TH mediates these effects remain unknown. Importantly, THs also induce expression of uncoupling proteins (UCPs), which are mitochondrial membrane proteins that dissipate the proton gradient as heat, rather than allow the gradient to be used to generate adenosine triphosphate. TH does not always enhance BMR. For example, TH does not enhance BMR in most regions of the brain, and the hormone actually suppresses metabolic activity in the pituitary gland. The TH receptors in these tissues are functional, suggesting that key mediators of TH regulation of BMR are blocked or absent.

THs exert multiple effects on the liver and are potent mitogens in this tissue, especially in growing animals. TH also influences multiple metabolic processes such as fatty acid β-oxidation and gluconeogenesis, both key aspects of the fasting response. However, TH can also stimulate expression of enzymes involved in lipogenesis and generation of NADPH-reducing equivalents that are required for fat synthesis and protection against reactive oxygen species. Because it is thought that fat oxidation and synthesis do not occur simultaneously, these processes are probably separated spatially or temporally, and TH must cooperate with other signaling mechanisms to regulate these effects. TR interacts directly with PPARα and PPARγ in regulation of some genes and may be a mediator for an indirect influence of thyroid status on metabolism.[66]

TH plays a major role in regulation of cholesterol metabolism in liver in rodents, and studies of patients with thyroid excess and deficiency states suggest that some of these pathways are also TH-regulated

TABLE 67.3 Thyroid Hormone Regulation of Metabolism

Tissue	Process	TR Isoform	Impact
BAT	Potentiation of adrenergic stimulation of BAT activity	TRα	Increased thermogenesis
BAT	Stimulation of UCP1	TRβ	Increased thermogenesis
WAT	Direct and adrenergic potentiation, induction of lipolysis	TRα/TRβ	Reduce lipid stores, increased energy expenditure
Liver/WAT	Lipogenesis	TRβ	Restore lipid stores
Liver	Coupling of autophagy to mitochondrial fatty acid oxidation	TRβ	Reduce hepatic lipid stores
Liver	Reverse cholesterol transport	TRβ	Reduce serum cholesterol
Liver	Increase expression of LDL Receptor	TRβ	Reduce serum cholesterol
Liver	Reduced hepatic fat deposition	TRβ	Reduce hepatic lipid stores

BAT, Brown adipose tissue; *WAT*, white adipose tissue; *TR*, thyroid hormone receptor.
From Sinha RA, Singh BK, Yen PM. Direct effects of thyroid hormones on hepatic lipid metabolism. *Nat Rev Endocrinol*. 2018;14:259–269 and Mullur R, Liu YY, Brent GA. Thyroid hormone regulation of metabolism. *Physiol Rev*. 2014;94:355–382.

in humans.[91] TH induces expression of enzymes involved in cholesterol synthesis but also increases levels of the low-density lipoprotein (LDL) cholesterol receptor, which promotes cholesterol uptake from the circulation. Likewise, TH increases expression of apolipoprotein A1, a key protein component of high-density lipoprotein (HDL), and increases expression of an HDL receptor (SR-B1). Consequently, TH excess may promote increased cholesterol flux from the plasma to the liver through both the LDL and HDL pathways. Additionally, TH stimulates cholesterol efflux and cholesterol-to–bile acid conversion. More recently, TH has been shown to directly stimulate autophagy. Collectively, these mechanisms account for the net reductions of serum cholesterol levels that are observed with TH and the net reverse cholesterol transport reflected by an increased flow of bile acids into the gut.

TH activation of lipolysis, reduction in serum cholesterol, as well as autophagy in the liver and reduction in liver fat storage, are attractive targets to treat a range of metabolic disorders.[91] TH analogs with more selective activation of TRβ and hepatic action were very effective in lowering cholesterol in statin failure patients, but use was limited by action on cartilage in animal models. TH and analogs have been effective for regression of hepatic steatosis in animal models and some clinical studies and remain an active area of clinical development.

KEY POINTS

- Thyroid hormone induces expression of the low-density-lipoprotein cholesterol receptor, apolipoprotein A1, a key protein component of high-density lipoprotein (HDL), and increases expression of an HDL receptor (SR-B1), with a net reduction of serum cholesterol levels and net reverse cholesterol transport, reflected by an increased flow of bile acids into the gut.

White and Brown Adipose Tissue

THs promote differentiation of precursors into white fat and induces lipogenic enzymes in preadipocytes from young rats and cell lines, but they also increase lipolysis in animals and humans.[66] However, the lipolytic effects predominates, because there is a net loss of fat in thyrotoxic states and a gain in hypothyroidism. It is thought that the lipogenesis is in response to the lipolysis in order to restore fat deposits. Hyperthyroidism is associated with loss of both fat and lean body mass, in most patients proportional to the elevation in TH levels. In contrast, hypothyroidism is generally associated with only a modest increase in fat mass.

TH stimulates adaptive thermogenesis in brown adipose tissues. In cold or in response to overeating, there is increased local production of T3 via induction of Dio2, shown to be due to a ubiquitination/deubiquitination, where adrenergic signaling and low T4 promote deubiquitination of Dio2 and increase local Dio2 activity. Thus, T3 cooperates with norepinephrine outputs from the sympathetic nervous system to induce UCPs that promote dissipation of the mitochondrial protein gradient as heat. There is a TR isoform specificity, with TRβ mediating TH stimulation of UCP1 gene expression,[92] and TRα potentiating TH-mediated adrenergic signaling.[93] Whereas previous reports suggested that adaptive thermogenesis was only important for temperature regulation in human newborns and in small mammals, studies have suggested that brown fat may also be important in adult humans.

Skin

TH is important for skin function, and TH imbalances are often first manifested in changes in appearance.[94] Hypothyroidism leads to cold, dry, and thickened skin. There is also increased hair loss. Conversely, hyperthyroidism leads to warm, moist, and smooth skin with fine, soft hair. Hormone effects are a combination of inhibitory changes in keratin expression, sterol biosynthesis, diminished sebaceous gland secretion, and increased collagen breakdown.[95] TH, when applied topically, has been shown to promote hair growth and wound repair.[94,96] TH has specific action on hair follicle stem cells and mediates the effects seen on hair changes as a result of changes in thyroid status.[97] The role of TH metabolism by Dio2 and Dio3 in the regulation of skin cancer growth and differentiation has been reported, including in melanoma and in basal and squamous cell carcinoma. T3 has been shown to be a significant inducer of the epithelial to mesenchymal transition in squamous cell carcinoma of the skin.[98] An increase in local T3 from Dio2 action, and reduction of inactivation by Dio3, promotes tumor growth and invasion.

LESSONS FROM RESISTANCE TO THYROID HORMONE RECEPTOR BETA AND ALPHA

The majority of studies that have identified TR isoform–specific actions were based on models with introduced mutations or TR gene deletions in mice, zebrafish, and frogs. Although these approaches have provided important insights, ultimately, the phenotypes of humans with mutations in genes important in TH signaling are most informative for understanding TH action. The genetic defects of TH signaling involving TR genes are now classified as RTH beta, associated with mutations in the *Thrb* gene, and RTH alpha, due to mutations in the *Thra* gene. These syndromes are discussed in detail elsewhere (see Chapter 81), but the connection between genotype and phenotype in individuals with RTH will be briefly discussed for the insights provided into tissue-specific actions of TH and the role of TR isoforms.

Resistance to Thyroid Hormone Beta

RTH beta is due to mutations in the *THRB* locus and is inherited in an autosomal dominant fashion. In most cases, patients are heterozygous for *Thrb* mutations, and the clinical signs and symptoms suggest that there is inhibition of endogenous functional TRs by the mutant receptor through a “dominant negative effect.” This explains the lack of negative feedback in the HPT axis, mediated by TRβ, which results in elevation of serum TSH and circulating TH levels. Since the central feedback regulation is blunted, circulating serum T4 and T3 are elevated, producing a “compensation” for reduced signaling at tissues with TRβ predominance. In tissues with TRα predominance, such as the heart, then there are signs of excess TH, with tachycardia. Metabolic regulation is also predominantly mediated by TRα, and RTH beta individuals have increased metabolism, higher resting energy expenditure, and a higher calorie intake compared with unaffected matched controls, without an increase in weight.[99] In a range of genetic models, there was a recapitulation of the primary biochemical phenotype of RTH, elevated blood levels of T4 and T3, and a high, nonsuppressible TSH. The high TSH levels in mice induces goiter, which is also a common clinical sign found in RTH beta patients.

Resistance to Thyroid Hormone Alpha

Thra mutations have no significant alterations in circulating TSH or T4 levels, suggesting that central TH feedback at the level of the hypothalamus and pituitary is not impaired. RTH alpha patients have an increase in serum T3 concentrations, increased T3/T4 ratios, and reduced serum reverse T3 concentrations, consistent with a reduction in Dio3 activity. This finding supports an earlier study that showed that upregulation of Dio3 by T3 is mediated by TRα.[100] Patients with *Thra* mutations present with signs suggesting hypothyroidism: short stature, delayed bone age, and clinical findings of dry skin and slow reflexes, and evidence for reduced TH action in key tissues, including delay in linear growth and tooth eruption, low serum insulin-like growth factor-1 levels, reduced muscle tone, impaired fine motor coordination, and severe constipation.[84] *In vitro* analysis of these TRα mutations reveals very low T3 binding affinity, defective activation from canonical TH response elements (TREs), repression of basal promoter activity, irreversible binding of corepressors, and a clear dominant negative effect. The response of these clinical manifestations of hypothyroidism to treatment with levothyroxine have been variable, with some improvement in growth if initiated in children and improvement of the metabolic and some cognitive manifestations in adults.[84]

KEY POINTS

- Findings from animal models regarding thyroid hormone (TH) receptor (TR) isoform specificity is confirmed by individuals with resistance to TH (RTH). In RTH beta, central feedback regulation is blunted and circulating serum T4 and T3 are elevated, producing a “compensation” for reduced signaling at tissues with TRβ predominance. In tissues with TRα predominance, there are signs of excess thyroid hormone, such as tachycardia and hypermetabolism. Patients with *Thra* mutations do not have this “compensation” and have manifestations of reduced TH action, short stature, delayed bone age, low serum insulin-like growth factor-1 levels, impaired fine motor coordination, and severe constipation.

SUMMARY AND FUTURE DIRECTIONS

TH is essential for normal development and regulates the function of a wide range of tissues in the adult. The use of animal models, including mice, zebrafish, and *Xenopus*, as well as analysis of human genetic disorders of thyroid signaling, has led to the recognition of multiple sites of regulation of TH action. The HPT axis closely regulates TH production and secretion from the thyroid gland. Additional sites of regulation include local tissue activation of the prohormone, T4, to the active form, T3, TH transporters in specific tissues, the amount and relative distribution of TR isoforms, and an important role of TR coactivators and corepressors. Newer areas of the mechanism of regulation that have been identified include posttranslational modification of TR by phosphorylation and sumoylation, subcellular localization of TR isoforms, and TH regulation of microRNAs. In addition to nuclear action, nongenomic actions of TH through membrane integrin receptors as well as modification of intracellular signaling pathways have been reported. A core action of TH is metabolic regulation, and many of these actions involve crosstalk with other metabolic signaling pathways, including PPARα and PPARγ. Genome-wide approaches have confirmed previous findings, such as the classic DNA TRE sequence, but have also shown indirect effects of TR, especially on chromatin remodeling and actions in regions without consensus TREs. TH signaling has a central role in metabolism, stem cell proliferation in development and regeneration after injury, brain development and function, retinal and ear development, cardiovascular function, and cancer. Greater understanding of these complex factors that regulate TH signaling will permit more detailed description of these interacting pathways, with the potential for selective therapeutic targets that impact these important processes.

INTRODUCTION

Thyroid disease is common, and the signs and symptoms of thyroid disease may resemble those of other disorders. Therefore, physicians frequently request so-called thyroid function tests even when they have a low suspicion of thyroid disease. Although these may include tests that directly assess thyroid gland activity, the most commonly requested thyroid function tests are those which determine the levels of thyrotropin (thyroid stimulating hormone [TSH]) and/or the individual thyroid hormones thyroxine (T4) and triiodothyronine (T3).

TSH is the key thyroid function test, because it is at the center of the hypothalamic-pituitary-thyroid axis. TSH is elevated if the thyroid gland fails to produce adequate thyroid hormone and suppressed if the thyroid gland produces too much. But there are other causes of an elevated or suppressed TSH, and measurement of thyroid hormone levels is often needed as well to verify that the cause of the abnormal TSH result is thyroid disease. Originally, this meant determining the total levels of T4 and T3, but the establishment of the so-called free hormone hypothesis—that the free or unbound hormone concentration, not the total, reflects thyroid hormone activity—resulted in assays designed to estimate the free T4 and free T3 fractions. There still is a role for measuring total T4 and T3, but free T4 is the most commonly requested test when the need to confirm the TSH level result arises.

This chapter describes measurement of the major thyroid function tests: TSH and free T4, as well as total T4 and T3 and free T3. The other laboratory tests that help in the diagnosis of thyroid disease (thyroglobulin and autoantibodies against the TSH receptor, thyroid peroxidase [TPO], and thyroglobulin) are described in the relevant chapters discussing the disorders they help diagnose.

THYROTROPIN

TSH is a glycoprotein hormone with a structure similar to other anterior pituitary glycoprotein hormones. They are noncovalently linked heterodimers of a common (alpha) chain and a unique (beta) chain, which contains the specific hormone's biological activity. TSH is considered the primary thyroid function test.[1] It is a useful screen for evidence of thyroid disorders and helps to monitor thyroid hormone replacement in patients with hypothyroidism, as well as thyroid hormone suppressive therapy in patients with thyroid carcinoma.

KEY POINTS

- Measurement of thyrotropin is the key thyroid function test, because it is at the center of the hypothalamic-pituitary-thyroid axis.

Immunoassay for Thyrotropin

The major advances in TSH testing involved moving from competitive to noncompetitive immunoassay approaches (Fig. 68.1). Routine measurement of TSH in clinical practice initially used competitive immunoassay techniques, in which TSH in the patient's serum competed with labeled TSH for anti-TSH antibody. Once separation of the bound from the unbound label was accomplished, the amount of label bound to antibody was inversely proportional to the concentration of TSH in the sample. These first-generation assays were useful for detecting elevated TSH levels, but they could not differentiate euthyroid from hyperthyroid patients with very low TSH levels. Noncompetitive immunoassays introduced in the 1980s achieved a level of analytical sensitivity that accomplished this differentiation (Fig. 68.2). These assays use one antibody to capture TSH and another, which is labeled, to bind to this complex. Once the unbound labeled antibody is removed, the amount of label bound to the solid phase is directly proportional to the concentration of TSH in the sample. This approach not only enhanced the ability to measure lower levels of TSH, but it expanded the measuring range on the high end as well. These second-generation TSH immunoassays quickly replaced the older ones. And by increasing the signal of the label on the labeled antibody and washing the solid-phase more efficiently, even greater analytical sensitivity was possible. Soon, so-called third-generation (and even fourth-generation) TSH assays were introduced. Today, almost all commercially available TSH immunoassays are capable of third-generation performance. Fourth-generation assays, including so-called single molecule immunoassays, are not widely used clinically.

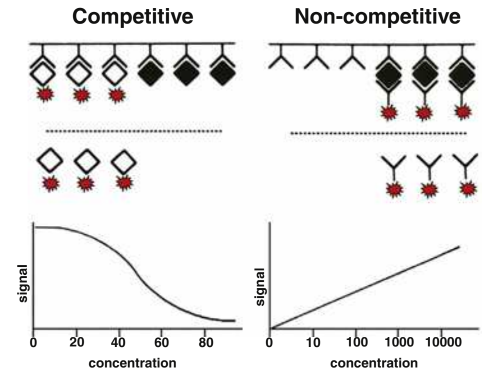

Fig. 68.1 Competitive versus noncompetitive immunoassay. The first immunoassays for thyrotropin (TSH) used a competitive approach (left) in which labeled TSH competes with the patient's hormone for a limited number of binding sites. The bound label is separated from the unbound label and the bound label (top) is inversely proportional to the patient's hormone concentration. Using a non-competitive approach (right) in which patient hormone is captured by bound and labeled antibodies, the bound label is proportional to the TSH concentration. This approach allows for measurement over a wider range and, more importantly, the ability to reliably detect lower levels of TSH is improved.

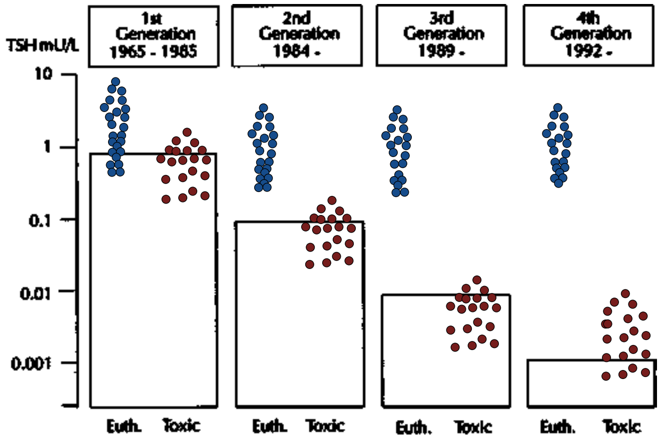

Fig. 68.2 Thyrotropin immunoassay generations. The first-generation assays were competitive immunoassays with limited analytical sensitivity. Differentiation of euthyroid (Euth) from hyperthyroid (Toxic) individuals was possible only when noncompetitive approaches were used. Enhancements improved the sensitivity of these second-generation assays, producing so-called third and even fourth generations, with even better separation.

KEY POINTS

- Today, almost all commercially available thyrotropin (TSH) immunoassays are capable of measuring TSH, with a reliable analytical sensitivity of 0.01 mU/L.

Performance of noncompetitive immunoassays for TSH is defined by so-called functional, rather than analytical, sensitivity. More modern terms for these distinctions are "limit of detection" (LOD, analogous to analytical sensitivity) and "limit of quantitation" (LOQ, analogous to functional sensitivity). The LOD is the lowest level of the TSH that can be distinguished from the background noise of the assay. The LOQ is the lowest level of TSH that can be measured with some degree of reliability, usually defined as reproducibility or precision over an extended period of time. The original LOQ target for TSH was the level below which the precision of the assay exceeded a coefficient of variability of 20%. By convention, second-, third-, and fourth-generation assays detect TSH with this degree of reproducibility down to levels of approximately 0.1, 0.01, and 0.001 mU/L, respectively. However, precision in the very low range for commercially available TSH immunoassays may not be as robust as it appears when functional sensitivity is initially evaluated. Also, many laboratories probably do not regularly monitor their performance in this range, and few proficiency programs regularly challenge laboratories at the limit of third-generation performance. Nonetheless, although the ability to better differentiate euthyroid from hyperthyroid patients is a useful feature, third-generation TSH assays are useful because the precision at higher levels (0.1–0.4 mU/L), where the results often impact clinical decisions, is markedly improved.

Thyrotropin Reference Intervals

Determining reference intervals for TSH is not straightforward. TSH does show diurnal variation, and significantly higher values have been recorded during the late evening and early night. However, because outpatient measurements are usually made during the day, this should have no significant impact on testing. Age does have an effect on TSH levels. Although only minimal changes occur during early adult life, observations that TSH levels rise with advanced age (without evidence of thyroid dysfunction) have raised the question of whether age-specific reference intervals should be implemented. In the absence of pregnancy, no significant gender differences have been observed. However, within these defined groups of euthyroid individuals, TSH levels do show significant interindividual variability.

There appears to be a consensus that the lower limit of the euthyroid reference interval for TSH should be approximately 0.4 mU/L. Therefore, the improved reproducibility in TSH measurement just below this cutoff is helpful. This range, representing potentially mild thyroid hormone excess but not overt hyperthyroidism, is an important one for clinical purposes. It may help to identify patients with subclinical hyperthyroidism and, when monitoring thyroid hormone replacement after thyroid ablation, to detect overtreatment with increased risk of atrial fibrillation. Significant hyperthyroidism due to Graves disease, functioning adenoma, or other causes is likely when the TSH level is truly "suppressed." This usually means less than 0.01 mU/L, because most commercially available TSH assays cannot reliably measure lower than this.

TSH assays are also especially important when hypothyroidism is suspected, because the inverse logarithmic relationship between TSH and T4 means that TSH levels will rise long before free T4 concentrations fall. Experts have disagreed with regard to the correct upper limit. The cutoff for an elevated TSH with first-generation TSH assays was approximately 10 mU/L. This fell to approximately 5 mU/L with the introduction of second- and third-generation assays. The major reason for this change was probably the reduced crossreactivity afforded by the use of monoclonal antibodies. A major problem with early TSH competitive immunoassays was crossreactivity with gonadotropins (luteinizing hormone, follicle-stimulating hormone, and human chorionic gonadotropin [hCG]), which share a common alpha subunit with TSH. For many years, most physicians have considered TSH levels greater than 10 mU/L as evidence of thyroid failure and levels between 5 and 10 mU/L as evidence of mild (or subclinical) hypothyroidism. During the past decade, however, there has been debate about the correct upper limit of the reference interval for TSH, as well as the approach to patients with subclinical hypothyroidism.

An analysis of thyroid function test results from a large survey of individuals chosen to represent the population of the United States (National Health and Nutrition Examination Survey) revealed that the mean TSH level in the general population was approximately 1.5 mU/L, with only a small degree of variability.[2] This finding prompted

TABLE 68.1 **Discrepancies Between Thyrotropin (TSH) and Free Thyroid Hormone Levels**

Elevated TSH Level Without Low FT4 or FT3 Levels	Low TSH Levels Without Elevated FT4 or FT3 Levels
Drugs that increase TSH concentration (cimetidine, dopamine antagonists, lithium, spironolactone, etc.)	Drugs that decrease TSH concentration (dopamine glucocorticoids, opiates, somatostatin, etc.)
Laboratory artifact (i.e., human antimouse antibody)	Laboratory artifact (i.e., biotin ingestion)
Nonthyroidal illness	Nonthyroidal illness
Recent increase in thyroid hormone replacement therapy	Recent decrease in suppressive thyroid hormone replacement
Subclinical hypothyroidism	Recent treatment for hyperthyroidism
Thyroid hormone resistance syndrome	Subclinical hyperthyroidism

FT3, Free triiodothyronine; *FT4,* free thyroxine.

organizations to call for lowering the upper limit of TSH to 4.0 mU/L, 3.0 mU/L, or even lower. These calls were resisted by many who worried that a significant number of patients would be unnecessarily labeled as having thyroid dysfunction, especially given the fact that there was no evidence that treatment of these individuals would provide any benefit. Because of concern that the population used to determine the range of TSH may have included individuals with occult thyroid disease, the data from the survey were reanalyzed to better clarify the relationship of TSH and antibodies to thyroid peroxidase (TPO), a recognized marker of autoimmune thyroid disease. TSH levels correlated with anti-TPO positivity, and the investigators found that TSH reference intervals determined with a population from which patients with occult autoimmune thyroid disorders had been excluded would indeed support the lower upper limit.[3] The issue of the upper limit for TSH remains controversial, especially because several studies since have demonstrated that most individuals with results slightly above these lower cutoffs have no evidence of thyroid disease.[4]

KEY POINTS

- There appears to be a consensus that the lower limit of the euthyroid reference interval for thyrotropin should be approximately 0.4 mIU/L, but experts have disagreed with regard to the correct upper limit.

Therefore, many other factors, including diet and nutrition, weight and body composition, genetic polymorphisms, and stressful stimuli apparently influence set points for the hypothalamic-pituitary-thyroid axis. A recently recognized factor, discussed later, that may account for some of the variability is the performance of the commercially available immunoassays for TSH. Several special situations have focused attention on other factors that influence TSH levels. One area that has always been problematic is pregnancy, which has a significant effect on thyroid function. TSH levels fall during the first trimester due to the thyroid-stimulating effect of hCG and then rise to baseline as hCG levels fall in the third trimester. Guidelines for the diagnosis and management of thyroid disease during pregnancy issued by the American Thyroid Association recommend trimester-specific reference intervals for TSH, as well as TSH targets for the diagnosis and treatment of thyroid disease during pregnancy.[5] As neonatal screening programs shift from T4 to TSH screening for congenital hypothyroidism, the appropriate cutoff for this indication is the subject of much debate. If screening is done during the first 24 hours after birth, programs must account for the neonatal surge in TSH production during this period. Also, even programs that screen at the traditional 2 to 4 days after birth are lowering the cutoff used in order to detect cases that would otherwise be missed.[6] Finally, a variety of stressful stimuli may suppress TSH production, including depression and other psychiatric diseases, sleep disorders, and the effects of severe systemic illness and/or major surgery (so-called nonthyroidal illness). Recovery from the latter may also result in a temporary elevation of TSH levels. Consequently, measurement of TSH in severely ill hospitalized patients should be done with caution.[7]

The inverse relationship between TSH and free T4 is log-linear in most individuals,[8] and this allows TSH to be considered as a single-test screen of thyroid function. In patients with primary hypothyroidism of whatever cause, levels should be elevated. The magnitude of serum TSH elevation correlates with the severity and, in part, the duration of thyroid hormone deficiency. Similarly, in patients with hyperthyroidism of whatever cause, levels should be lowered. If levels are below 0.01 mU/L (or the lowest limit reported by the laboratory), significant hyperthyroidism is probably present. TSH abnormalities may need to be further investigated using free T4 because of the variety of conditions that may cause TSH to be abnormal in the absence of either primary hypothyroidism or significant hyperthyroidism (Table 68.1).

KEY POINTS

- Thyrotropin (TSH) abnormalities may need to be further investigated using free T4, because a variety of conditions may cause TSH to be abnormal in the absence of either primary hypothyroidism or significant hyperthyroidism.

The hypothalamic tripeptide thyrotropin-releasing hormone (TRH) plays a central role in the regulation of pituitary TSH secretion. The TRH test measures the increase of pituitary TSH in serum in response to the administration of synthetic TRH. A direct correlation between basal serum TSH values and the maximal response to TRH has been observed. It could be useful in some situations, such as when there is suspicion of central hypothyroidism or a TSH-secreting pituitary adenoma. However, the use of modern sensitive immunoassays for TSH, plus the fact that TRH testing is no longer available in many areas, has decreased the need to perform this test.

Standardization of Thyrotropin Immunoassays

All strategies for defining abnormal TSH levels in different patient populations will suffer if all TSH immunoassays do not produce comparable results. Variability in the performance of TSH immunoassays has been apparent for several years. Data from proficiency testing programs have revealed poor correlation between observed method bias and the reference intervals recommended by the manufacturers (which are largely equivalent). Possible sources of variability include the specificity of the antibodies used, interferences from patient antibodies against the mouse monoclonal antibodies used, interferences from other endogenous substances such as biotin (for immunoassays that use biotin-streptavidin binding), and the TSH material used for calibration. TSH has three sites for the addition of oligosaccharides, and carbohydrate may constitute up to 25% of its mass. The pituitary releases a heterogeneous mixture of TSH glycoforms with regard to these side chains, and its nature changes when thyroid disease is present. Because the same assay is used to measure TSH in all patients, it is important that immunoassays measure TSH in an equimolar fashion.

All of these considerations were the impetus for the establishment of a Committee for Standardization of Thyroid Function Tests to study comparability of TSH assays (as well as total and free T4 and T3 immunoassays) under the auspices of the International Federation for Clinical Chemistry and Laboratory Medicine. Over the course of a decade, this committee worked with many *in vitro* diagnostic companies who provide TSH immunoassays to examine potential sources of variability, and potential solutions for standardization. Standardization of laboratory testing aims to ensure that all assays are traceable to a reference measurement procedure (RMP) and, consequently, all assays give equivalent results for any patient's specimen. The standard material for TSH is a World Health Organization International Reference Preparation obtained from purified cadaver pituitary. Because no RMP existed for TSH, the committee approached the problem using an alternative scheme called harmonization, in which a system consisting of methods and materials act as the reference. A panel of single-donation human blood serum specimens that spanned the TSH measurement range was tested by all manufacturers and TSH values were assigned to each sample using the "all-procedure trimmed mean." This target was used by assay manufacturers to recalibrate their individual methods. This approach has been well documented as a reliable way to ensure uniform results among different immunoassays.[9] The initial panel consisted of specimens from euthyroid individuals. The investigators showed that currently available TSH assays are precise, and that most agreed within plus or minus 10%. Recalibration was successful in reducing this variability. Recalibration with a panel of specimens from patients with thyroid disease was similarly successful and also demonstrated that there does not appear to be any effect of different TSH glycoforms on different assay performance. Finally, a study was conducted using a new panel of 120 specimens from presumably healthy individuals with negative testing for anti-TPO antibodies and TSH less than 10 mU/mL.[10] Recalibration was able to narrow the ranges of the reference intervals for each commercially available assay tested so that they showed much better agreement (Fig. 68.3). This indicates that TSH may be successfully harmonized in the near future, which may help the resolve some of the controversy regarding the appropriate upper limit to use for screening.

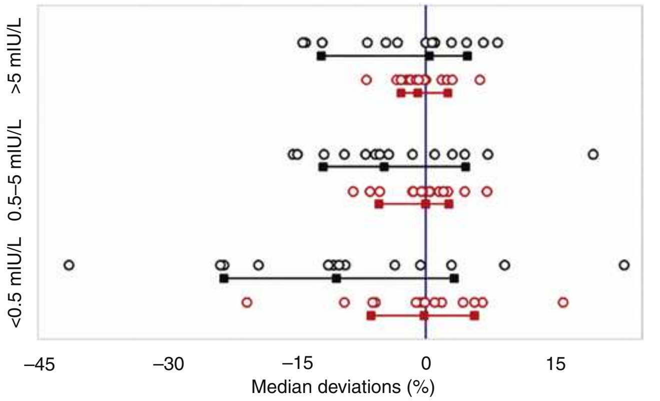

Fig. 68.3 **Harmonization of thyrotropin (TSH) immunoassays.** Median deviations of commercially available TSH immunoassays before *(black)* and after *(red)* recalibration using targets derived from a factored analysis of all of the results. The improvement is shown for specimens with low, normal, and high TSH levels. (From Thienpont LM, Van Uytfanghe K, De Grande LAC, et al. Harmonization of serum thyroid-stimulating hormone measurement paves the way for the adoption of a more uniform reference interval. *Clin Chem.* 2017;63:1248–1260. Reproduced with permission.)

FREE THYROID HORMONES

Thyroid hormones in the blood are bound to serum protein carriers, thus leaving only a minute fraction of free hormone in the circulation that is capable of mediating biological activities. A reversible equilibrium exists between bound and unbound hormone, and it is the latter that represents the fraction of the hormone capable of traversing cellular membranes to exert its effects on body tissues. This free hormone hypothesis forms the basis of the clinical approach to a number of endocrine disorders but this is especially true for thyroid disease. Most (approximately 99%) of the total T4 present in blood is bound, the majority to thyroxine-binding globulin (TBG). Even though it is present in a much lower concentration than the other major thyroid hormone–binding proteins (transthyretin and albumin), TBG has a significantly higher affinity for T4. Most experts agree that, in euthyroid individuals, the free T4 concentration is held constant, even when the concentration of the binding proteins change, while in thyroid disease it is abnormal. But estimating or measuring the very low concentration of free T4 has proved difficult over the years, and approaches have evolved.

Indirect Estimation of Free Thyroid Hormones

The first attempts to measure the free T4 concentration relied on an estimate of the number of binding sites available on the serum binding proteins. This was accomplished by adding labeled thyroid hormone to serum and, after incubation, using an absorbent material of some kind to collect all of the unbound labeled hormone. Labeled T3, for which TBG has a lower affinity, was used rather than labeled T4 in order to prevent the labeled hormone from displacing T4 bound to the protein. The so-called "T3 uptake" (T3U) test produced a result that correlated with the saturation of TBG with T4. If TBG saturation was high (as would be the case in hyperthyroidism), the uptake of labeled hormone by the absorbent would be high; if TBG saturation was low (as would be the case in hypothyroidism), the uptake of labeled hormone by the absorbent would be low. However, when the total T4 level was increased or decreased because of changes in TBG concentration, a baseline level of TBG saturation would have been achieved, and the uptake of the labeled hormone would be in the opposite direction. Calculation of a unitless figure called the free thyroxine index (FTI), the mathematical product of the total T4 (originally the protein-bound iodine) and the T3U, could thus be used to normalize changes in total T4 due to increases of decreases in TBG. Currently, labeled T4 analogs are used in place of T3 (so-called "T-uptake" assays), and another approach relies on measurement of TBG, with calculation of the T4/TBG ratio. Although FTI determinations were once commonly requested laboratory tests, they have been supplanted by more direct approaches, including equilibrium dialysis (or ultrafiltration) and immunoassay.

Free Thyroid Hormones by Equilibrium Dialysis

Early attempts to directly measure free T4 used equilibrium dialysis to physically separate free T4 from bound T4. But the initial approach was not direct but indirect. In direct equilibrium dialysis, free hormone in the specimen moves into a second compartment on the other side of a semipermeable membrane that excludes the protein-bound hormone. After an equilibrium between the two compartments is reached, the concentration of hormone in the second compartment is measured. However, because the free T4 is such a small percentage of the total, T4 concentrations in the second compartment were far

Fig. 68.4 **Equilibrium dialysis (ED) measurement of free thyroxine (T4).** The first approach to equilibrium dialysis for free T4 used an indirect approach *(top)* in which radioactively labeled T4 was added to the sample, and the amount of label in the dialysate was used along with the total T4 measured separately to estimate the free T4. In the modern direct approach *(bottom)*, the T4 in the dialysate is measured using mass spectrometry. Note that the amount of protein-bound T4 in actual samples would be much greater than the percentage shown, so disruption of the equilibrium between bound and free T4 would not be significantly disturbed.

below the ability of early immunoassays to measure it. Consequently, most investigators took an indirect approach by adding a trace amount of radioactive-labeled T4 to the specimen (Fig. 68.4). This labeled T4 equilibrated with the respective bound and free endogenous T4 and the free fraction could be calculated from the proportion of labeled hormone in the dialysate.

An equilibrium method that used immunoassay to directly measure T4 in the dialysate was introduced in the 1990s. Unfortunately, this product is no longer widely commercially available. More recently, a direct equilibrium method was developed and proposed as an RMP. The details of this procedure include strict requirements for the buffer used, the pH of the specimen, the dialysate membrane cutoff size, the size of the two compartments, and the temperature. The T4 in the dialysate is measured by isotope dilution–liquid chromatography/tandem mass spectrometry (LC-MS/MS), not immunoassay. Other alternative direct approaches, such as ultrafiltration followed by LC-MS/MS, have also been described. There is debate regarding which is the best approach, but either is probably too laborious to be implemented for routine clinical use. Therefore, most clinical laboratories rely on commercially available immunoassays.[11]

KEY POINTS

- A direct equilibrium method for measurement of free thyroxine has been developed and proposed as a reference measurement procedure.

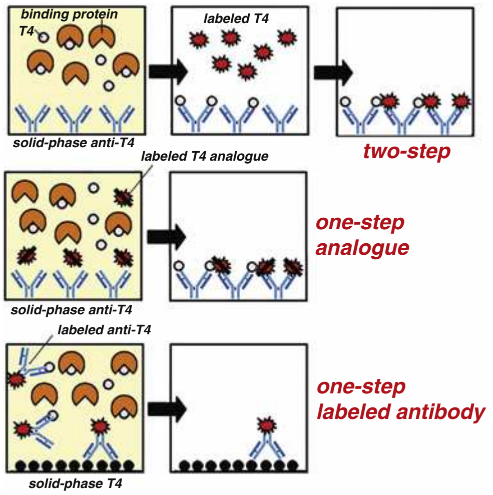

Fig. 68.5 **Free thyroxine (T4) immunoassay.** All of the commercially available immunoassays for free T4 use one of these three approaches (described in the text).

Immunoassay of Free Thyroid Hormones

There have been three formats used for free T4 immunoassay. All utilize competitive immunoassay with a solid support that can be washed, removing unbound labeled reagent. But each is very different (Fig. 68.5).

In the so-called two-step method, free hormone in the specimen interacts with antihormone antibody on a solid support, which becomes occupied by endogenous free hormone to a smaller or larger extent based on the free hormone concentration. The specimen is then removed, and excess labeled hormone is added, which fills any empty antibody binding sites. This is also often referred to as "back-titration." In the labeled analogue approach (also commonly referred to as a "one-step" method), free hormone in the specimen interacts with antihormone antibody on a solid support *in the presence of* labeled hormone. In order to prevent interaction of labeled hormone with binding proteins, the T4 used as the labeled hormone is altered in a way that is meant to interfere with binding to endogenous proteins but not with antibody binding. The nature of these so-called hormone "analogs" is proprietary. Finally, the "labeled antibody" method (which is also a "one-step" assay) avoids the use of labeled hormone entirely. Free hormone in the specimen interacts with labeled *antibody* in the presence of solid-phase hormone. Some critics have pointed out that this solid-phase hormone is also an "analog," but the fact that it is not able to enter the free hormone pool in the same way as the soluble analog probably limits its ability to compete with the endogenous free hormone for endogenous binding sites. For all three formats, the amount of labeled reagent left on the solid-phase after final washing is inversely proportional to the original concentration of free hormone in the specimen.[12]

There are significant discrepancies between different commercially available immunoassays for the measurement of free T4. Although different calibration may explain some of the overall differences (see later), the ways in which different assays influence the equilibrium between protein-bound and free hormone in individual patients may also explain many of the discrepancies. Although the labeled T4 analog used in one-step analog assays should not bind to any of the endogenous binding proteins, it initially appeared that some analogs did exhibit significant binding to albumin. Free T4 concentrations in patient specimens with albumin levels different from those of the calibrators used in the assay would either be overestimated or underestimated. Because patients who are critically ill often have low albumin levels, free T4 assays frequently underestimated the true free T4 concentration. However, most manufacturers have addressed this problem, either by adding albumin to the reagent (so that any variation in the patient's albumin level will be compensated) or by improving the behavior of the T4 analog.

Another problem is the influence of the total concentration of protein-bound T4, especially the fraction bound to TBG, because of its high affinity for T4, as well as the fact that it may be present in a wide range of concentrations. Generally speaking, immunoassays have been shown to underrecover free T4 when TBG levels are elevated, although the validity of the design of these investigations (using artificial T4 solutions with added T4-binding proteins) has been criticized. This limitation has often been cited as a reason to question the accuracy of free T4 concentrations in pregnant women, especially in the third trimester (see later).

Finally, for both one-step analog and two-step back-titration immunoassays, consideration must also be given to the amount of anti-T4 antibody used on the solid phase. It is very important that binding of free T4 to the anti-T4 antibody occur without significantly disturbing the equilibrium between free T4 and protein-bound T4. If this happens, protein-bound T4 may dissociate. This phenomenon is called sequestration. The antibody reagent should not remove more than 1% of the total T4 in the specimen. Even though this represents more than the free moiety, it represents only a small percentage of the total T4 present and is unlikely to significantly disturb the equilibrium. Dilution has been traditionally used to gauge the degree to which a free T4 immunoassay is susceptible to this effect, either because of the amount of reagent antibody present or the affinity of the antibody used. Assays are considered robust as long as this effect is kept to a minimum.[14]

Commercially available immunoassays for free T3 have been developed, using approaches similar to those used for free T4, and free T3 is often requested instead of total T3. The same issues that may influence assays for free T4 can impact assays for free T3. The Clinical Laboratory Standards Institute has issued an approved guideline for the measurement of free thyroid hormones.[13] Although it is unlikely that many clinical laboratories will be able to utilize the proposed RMPs for free T4 and free T3, they should be able to implement several of this guideline's recommendations for ensuring that free thyroid hormone results using commercially available immunoassays are as accurate and precise as possible. These include adding increasing amounts of albumin and TBG to specimens from euthyroid individuals, as well as diluting specimens from euthyroid individuals using inert buffer in order to assess possible analog binding, the effect of binding proteins, and the degree of antibody sequestering. The guideline also recommends verifying the performance of the free T4 immunoassay in specimens from the following groups of patients: euthyroid; hyperthyroid; hypothyroid; patients with elevated TBG concentrations; and patients who are taking drugs known to compete for T4 binding sites on TBG and albumin.

KEY POINTS

- Guidelines exist for ensuring that free thyroid hormone results using commercially available immunoassays are as accurate and precise as possible, but there are significant discrepancies between different commercially available immunoassays for the measurement of free thyroxine.

Free Thyroid Hormone Reference Intervals

Reference intervals for both free T4 and free T3 vary with the manufacturers of commercially available assays, but are approximately 0.8 to 2.0 ng/dL (10–26 pmoL/L) for free T4 and 0.2 to 0.4 ng/dL (3-6 pmol/L) for free T3. With few exceptions, the free T4 and free T3 concentrations are high in hyperthyroidism, low in hypothyroidism, and normal in euthyroidism, even in the presence of changes in TBG concentration. The condition that has raised the most concern about free thyroid hormone reference intervals is pregnancy. The influence of elevated TBG on immunoassays for free T4 is especially pronounced in pregnancy. Although so-called hypothyroxinemia of pregnancy does exist and needs to be recognized, euthyroid reference intervals in the second and third trimesters should probably be lower than previously thought. Guidelines of the American Thyroid Association for management of thyroid disease during pregnancy recommend that the laboratories develop trimester-specific reference intervals for the free T4 assay used. However, because of concerns about the performance of free T4 immunoassays, they also include a recommendation to use either equilibrium dialysis or ultrafiltration. Because neither direct approach is likely to be widely available, the guidelines suggest alternatives such as the use of total T4 (with trimester-specific reference intervals) or the free thyroxine index using T-uptake assays.[5] However, the use of either alternative suggested by the guidelines may not properly classify pregnant patients.[15] Immunoassays have been shown to correlate with equilibrium dialysis; although levels using immunoassay may be lower, the trending is similar,[16] but variability between different commercially available assays may classify patients differently.[17]

KEY POINTS

- There is probably still a lack of consensus regarding the use of free thyroxine assays in pregnancy.

Standardization of Free Thyroid Hormones

The same group that looked at harmonization of TSH measurements also examined commercially available immunoassays for free T4 and free T3, working in partnership with the same manufacturers. Except for one, the results were all considerably lower than those using the equilibrium dialysis RMP. However, the good news was that most of the bias appeared not to be related to any of the assay issues discussed previously, but rather to the calibration employed by the individual manufacturers. Mathematical recalibration using the regression of the results by each assay to the target values determined by the equilibrium dialysis RMP was able to remove most of the aforementioned considerable systematic bias (Fig. 68.6). This approach to standardization was pursued extensively for free T4 immunoassays in a similar fashion to that used for TSH and culminated with a similar study showing that removal of assay-specific bias may be able to align the different reference intervals to that of the RMP. The ability to share the RMP reference interval was not initially fully successful using a stringent requirement for the location of the upper and lower cutoffs to be within the confidence limits of the RMP. This was attributed to the susceptibility of free hormone immunoassays to a variety of individual

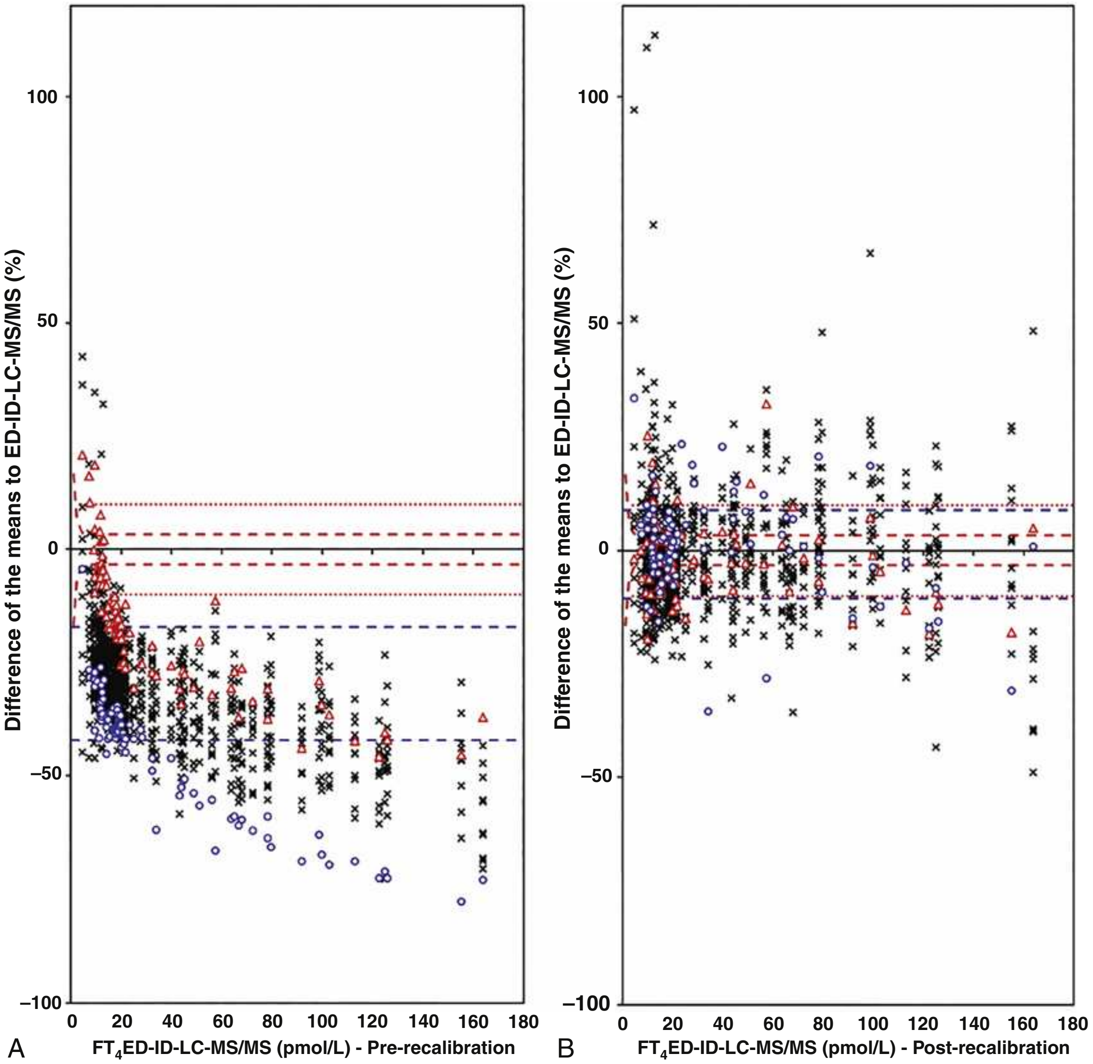

Fig. 68.6 **Standardization of free thyroxine (T4) immunoassays.** Comparison of commercially available immunoassays for free T4 to the equilibrium dialysis reference measurement procedure before *(left)* and after *(right)* recalibration. The initially most discrepant assays (high or low) are shown in red and blue, respectively. Although there was still significant variability for some of the assays, recalibration shifted the overall percentiles (15th and 18th) to within the bias expected based on biological variation *(red dotted lines). ED-ID-LC-MS/MS*, isotope dilution–liquid chromatography/tandem mass spectrometry; *FT_4*, free thyroxine. (From De Grande LAC, Van Uytfanghe K, Reynders D, et al. Standardization of free thyroxine measurements allows the adoption of a more uniform reference interval. *Clin Chem.* 2017;63:1642–1652. Reproduced with permission.)

sample related effects and/or variability in the lots of the reagents used by the manufacturers. However, using a slightly less stringent requirement, the hope for an eventual uniform reference interval for free T4 appeared within reach.[18]

TOTAL THYROXINE AND TRIIODOTHYRONINE

Although the primary focus of the use of thyroid function tests is the combination of TSH and free T4, there are still situations where the traditional measurement of the total level of T4 and T3 is helpful. The major secretory product of the thyroid gland is T4 in a ratio favoring T4 over T3 by 10- to 20-fold. Because they are present in higher concentrations and are not subject to the same specimen issues as free hormones, total T4 and T3 are easier to measure. Assays for total T4 and T3 use competitive immunoassay and include a reagent such as 8-anilinonaphthalene sulfonic acid that blocks T4 and T3 binding to serum proteins, so that total hormone is available for competition with the assay antibody.

The usual concentration of total T4 in adults ranges from 5 to 12 microg/dL (64–154 nmol/L). The usual concentration of total T3 in adults ranges from 80 to 190 ng/dL (1.2–2.9 nmol/L). Although levels of total T4 and T3 above and below these ranges are usually associated with hyperthyroidism and hypothyroidism, respectively, the total levels do not always correspond to the free hormone concentrations. When concentrations are below or above these ranges in the absence of thyroid dysfunction, they are usually the result of an abnormal level of serum TBG. Such abnormalities are commonly seen during pregnancy or the administration of estrogen-containing compounds, which result in a significant elevation of serum total T4 levels in euthyroid individuals. Similarly, total T4 levels are low in conditions that are associated with decreased TBG concentrations, but the free T4 is usually normal. The total T4 concentration in serum may be also be altered by alterations in T4 binding to TBG or compensatory changes due to defects in the conversion of T4 to T3. Although changes in transthyretin concentration rarely give rise to significant alterations in total T4 concentration, the presence of a variant serum albumin in patients with familial dysalbuminemic hyperthyroxinemia with high affinity for T4 produce apparent elevations in the measured total T4 concentration, whereas the free T4 levels remains normal.

The ratio of total T3 to total T4 may sometimes be helpful in the evaluation of patients with hyperthyroidism. A low ratio may favor thyroiditis or iodine-induced hyperthyroidism over Graves disease. A high ratio may be a helpful prognostic marker after initial of antithyroid treatment of Graves disease.

KEY POINTS

- Although the primary focus of the use of thyroid function tests is the combination of thyrotropin and free thyroxine (T4), there are still situations where the traditional measurement of the total level of T4 and triiodothyronine is helpful.

INTERFERENCE IN THE MEASUREMENT OF THYROID HORMONES

When there is discrepancy between the results of a laboratory test and the patient's clinical presentation, interferences with the assay itself must be considered. Traditional problems such as crossreactivity of the antibody used have largely been eliminated. Some interferences specific for TSH and free T4 immunoassays have been discussed, but there are several categories that may influence the results of all assays. Endogenous antibodies that react with any of the assay reagents may cause a falsely low or high result, depending on the format of the assay. This category includes human antimouse antibody, antibodies against the hormone being measured, or rheumatoid factor. Other endogenous substances may interfere in other ways. A recent focus has been the effect of biotin, used in the treatment of rare metabolic disorders but also taken in high amounts as a nutritional supplement. Immunoassays that use the binding of biotin to streptavidin in order to measure the bound label may produce erroneous results in patients with high levels, again in a way that is dependent on the format of the assay.[19] Finally, a large number of drugs may produce discrepant results. These effects are less likely to be assay interferences, but rather alterations in thyroid hormone physiology. These include agents that inhibit thyroid hormone synthesis and secretion, affect thyroid hormone binding proteins, or alter thyroid hormone metabolism.[20]

If some assay interference is suspected, a good first step is to repeat the testing using another manufacturer's method that has a different assay format. Diluting the specimen in the hopes of diluting out the effect of the interfering substance without affecting the measuring range of the assay or attempting removal of immunoglobulin in case the interference is due to an endogenous antibody may also help. When the presence of a drug interfering with endogenous thyroid function or metabolism is suspected, it may be necessary to temporarily withhold the drug and repeat the testing.[21]

FUTURE DIRECTIONS

TSH will continue to be the key thyroid function test when screening for thyroid dysfunction, and the efforts directed at harmonization of the commercially available assays will be successful. This will help investigators continue to evaluate the relationship between TSH levels and thyroid hormone activity in the general population and may allow the controversy regarding the appropriate upper limit of the reference interval to be resolved. Free T4, rather than total T4 or either total T3 or free T3, will continue to be used to confirm abnormal TSH results. Some have advocated more routine use of equilibrium dialysis for free T4 measurement, but this will not be feasible in the near future, and laboratories will continue to use commercially available immunoassays. The efforts directed at standardization of free T4 immunoassays will be hampered by several factors, including the various formats used, the differences in the influence of specimen-specific effects, and the fact that most of the current methods produce results that are significantly lower than the equilibrium dialysis RMP. Although standardization will allow for better patient care, a major education initiative will be needed if it is accomplished. Finally, trimester-specific reference intervals for thyroid function tests in pregnancy will be widely adopted.

ULTRASONOGRAPHY

Indications for Sonographic Assessment

Thyroid nodules are a common clinical entity, with up to 70% of patients over the age of 70 years harboring this neoplasm.[1] While the majority of nodules represent a benign neoplasm, and most malignant lesions are associated with an excellent prognosis, up to a quarter of patients with carcinoma have larger, higher-stage tumors at initial diagnosis.[2] Thus, it is incumbent upon the clinician to triage nodules efficiently and effectively. Current guidelines, therefore, uniformly recommend sonography as the initial step in the evaluation of a patient suspected of having a thyroid nodule.[3-5]

The physical examination of the neck is an insensitive means of identification of thyroid nodules. Palpation alone only identifies nodules in approximately 5% of patients,[1] whereas screening ultrasound (US) may reveal a nodule in over 37% of patients, with incidence escalating with age.[6] When a nodule is suspected on exam, US is essential to confirm the exam finding. One retrospective study of patients with suspected thyroid nodules identified on palpation found no corresponding lesion in 16% of patients. Further, another nodule that was not palpated was identified elsewhere in the gland in 23% of patients.[7] In this particular study, the US findings changed the management plan in 63% of patients.[7]

Physics of Ultrasonography

It is important to have at least a basic understanding of the verbiage used in thyroid sonography and the physics behind the findings. Echogenicity is essentially describing the color of a nodule or the thyroid itself with specific modifiers to compare to surrounding normal anatomy. Isoechoic describes echogenicity that is of the same color as normal thyroid tissue. The term hypoechoic is used to describe a lesion or gland that is darker than normal thyroid tissue, whereas hyperechoic is brighter. Echotexture is a term used to describe the pattern of tissue being examined; a normal thyroid is defined as having a homogeneous echotexture (Fig. 69.1A). In contrast, the echotexture of a gland involved with lymphocytic thyroiditis may have a heterogeneous echotexture (see Fig. 69.1B). This concept will be discussed in greater detail in the section later on diffuse thyroid disorders.

The sonographic appearance of a normal thyroid is one of a uniformly medium gray echotexture that is midway in hue between the lighter fascia and the darker musculature surrounding the gland (Fig. 69.e1). A healthy thyroid appears relatively bright on US due to its follicular architecture, which is composed of lakes of colloid surrounded by a thin layer of follicular cells. The degree of reflected sound waves directly impacts the brightness of the resulting image; greater reflection results in a brighter image. As the US wave travels through soft tissues of any type, a portion of the sound wave is reflected back to the probe when it encounters the interface of two tissues with unequal acoustic impedance (or resistance to the US wave traveling through a tissue). There is a dramatic mismatch in acoustic impedance between follicular cells and colloid; consequently, a large fraction of the US wave is reflected back to the probe when a sound wave encounters a follicle. Because there are innumerable follicles in a healthy thyroid, there is a significant amount of reflection of the US wave back to the probe. The result is a relatively bright-appearing thyroid. In contrast, tissue that is relatively homogeneous in histologic composition will have minimal reflection of the US wave back to the probe. The resultant image is uniformly dark. Understanding the physics behind this phenomenon of acoustic impedance is important when examining thyroid tissue and nodules, as it provides insight into the underlying pathophysiology of the disease process (Fig. 69.e2).

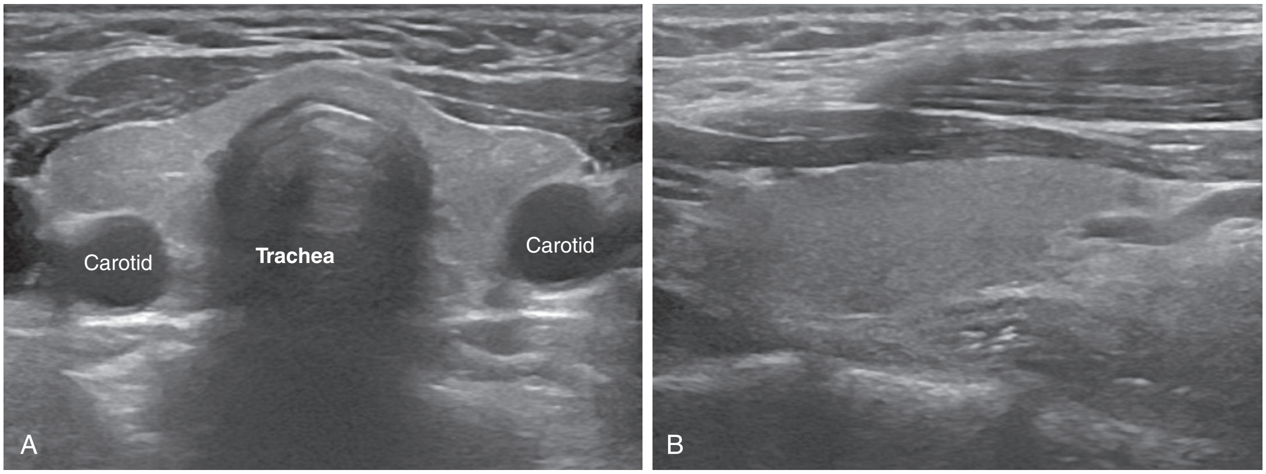

Fig. 69.e1 A, Diagnostic image of an ultrasound of a normal thyroid gland on transverse imaging with labels identifying the surrounding anatomic landmarks. B, Diagnostic image of an ultrasound of a normal thyroid gland in the sagittal view.

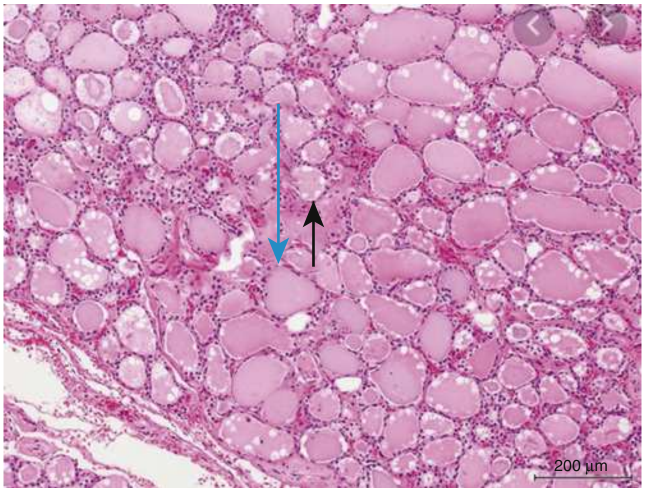

Fig. 69.e2 Photomicrograph of normal thyroid follicular architecture. The larger, blue arrow represents ultrasound waves traveling from the probe. When it encounters the follicle, some of the US wave is reflected back to the probe due to the change in acoustic impedance represented by the smaller, black arrow.

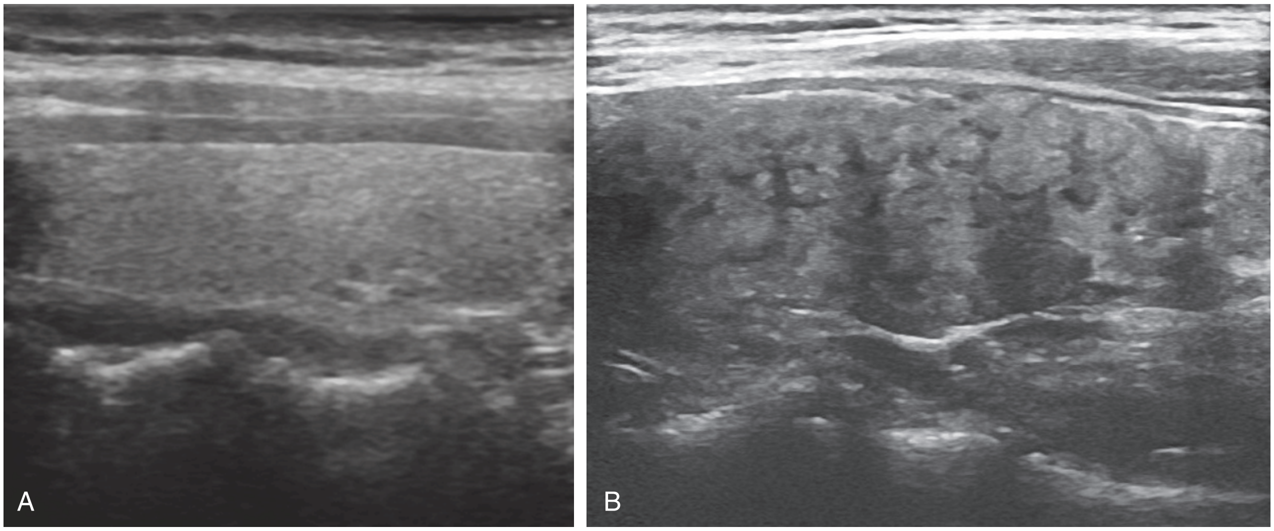

Fig. 69.1 A, Diagnostic image of a normal thyroid ultrasound in the sagittal view. Notice the medium gray color of the gland compared to the surrounding musculature and fascia. B, Diagnostic image of a thyroid ultrasound showing Hashimoto's thyroiditis. The thyroid is diffusely heterogeneous in echotexture. This diffuse micronodular appearance has been called a "giraffe pattern."

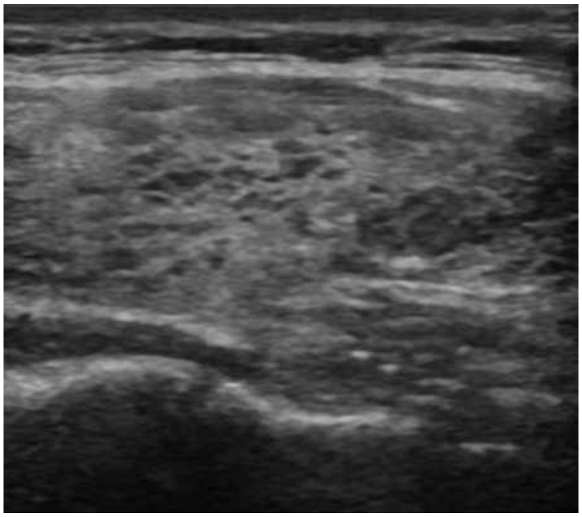

Fig. 69.2 Diagnostic image of a thyroid ultrasound showing Hashimoto's thyroiditis. The gland is heterogeneous with a microcystic echotexture due to small areas of germinal centers.

Diffuse Thyroid Disorders

Lymphocytic Thyroiditis. Lymphocytic thyroiditis is readily visible on sonography; the identification of diffuse heterogeneity in thyroid echotexture is a cardinal feature. Additional descriptors that may be reported in lymphocytic thyroiditis include a micronodular or microcystic echotexture (Fig. 69.2). The lymphocytic infiltrate produces a change in the histologic architecture of the normal thyroid tissue described earlier. This destruction of the normal follicular unit and replacement with sheets of lymphocytes alters the dynamics of US waves as they travel through the gland. The lymphocytic infiltrates appear as dark areas on US because the acoustic interface of follicular cells and colloid is replaced with a more uniform inflammatory process. Consequently, the US wave is not reflected back to the probe with the same intensity, and the lymphocytic infiltrate appears dark. In the early stages of the disease, the spared areas of the gland appear isoechoic, while the germinal centers appear dark, resulting in an overall heterogeneous echotexture of the gland (see Fig. 69.1B). As the disease progresses, the entirety of the gland is encompassed by the inflammatory process and may become diffusely hypoechoic (Fig. 69.e3A–C).

Hashimoto's Thyroiditis. US of the neck can have an important role in the diagnosis of Hashimoto's thyroiditis. Reliance on clinical and biochemical findings alone to diagnose Hashimoto's thyroiditis would miss half of patients with disease; including the sonographic analysis significantly improves the diagnostic sensitivity and specificity.[8,9] The characteristic sonographic appearance of Hashimoto's thyroiditis includes a diffusely heterogeneous parenchyma with hypoechoic areas interspersed with normal thyroid tissue; identification of this US feature has a positive predictive value of 95%[10] (see Fig. 69.1B). The vascularity of the gland may be variable, but is often increased early in the disease course. In the later stages of the disease, there may be a reduction in the vascularity with eventual avascularity as the degree of fibrosis increases (Fig. 69.e4). Echogenic septations, caused by fibrosis of the parenchyma, may be seen throughout the gland.

Another important feature associated with Hashimoto's thyroiditis includes surrounding reactive or hypertrophic lymphadenopathy. These nodes appear plump and may have a characteristic hilar stripe. They are typically seen anterior to the trachea and inferior to the thyroid gland, though they may also be seen in the lateral neck at levels II and IV (Fig. 69.e5).

KEY POINTS

- Hashimoto's thyroiditis is easily identified on ultrasound. The gland is marked by varying degrees of hypoechogenicity, with pseudonodules and septations. The presence of surrounding reactive adenopathy is also a clue to the underlying diagnosis of Hashimoto's.

Graves Disease. The sonographic appearance of Graves disease is similar to that seen in Hashimoto's thyroiditis but tends to be more diffusely involved; the micronodular pattern is less commonly seen (Fig. 69.3A). Generally, the gland is enlarged with a diffuse hypoechoic echotexture. Increased vascularity is a prominent component of the examination, particularly in untreated glands. This sonographic

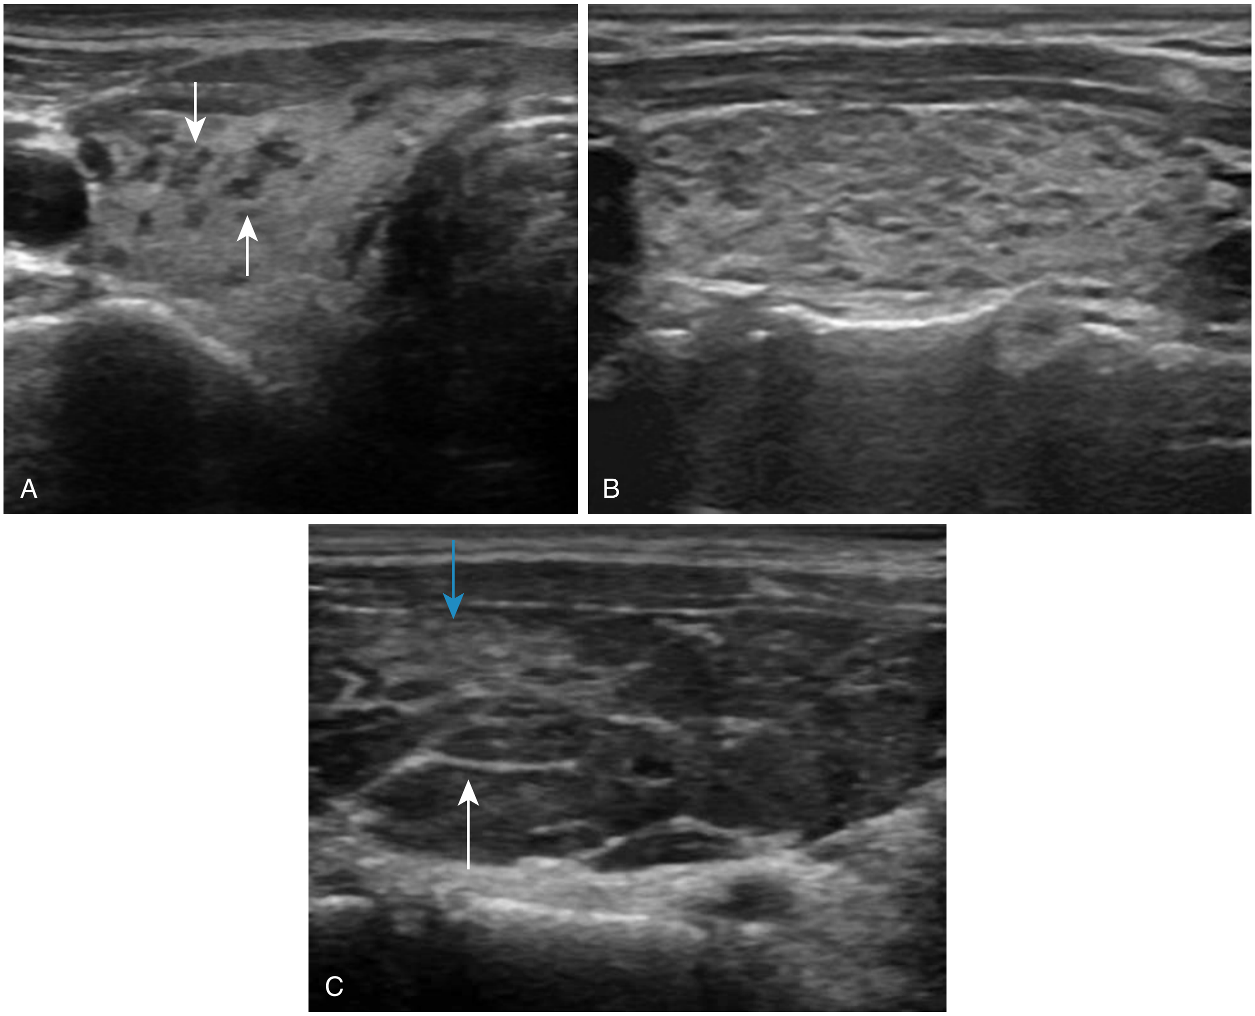

Fig. 69.e3 A, Diagnostic image of an ultrasound demonstrating early stage Hashimoto's thyroiditis with a microcystic or "moth-eaten" pattern marked by the small white arrows. B, Diagnostic image of an ultrasound of the thyroid illustrating progression of lymphocytic thyroiditis. Notice the more diffuse involvement of the lobe and the microcystic pattern. C, Diagnostic image of an ultrasound of a thyroid gland with chronic lymphocytic thyroiditis (Hashimoto's thyroiditis). The gland is diffusely hypoechoic with bright linear bands (white arrow), which represent fibrotic septations. Anteriorly an area of hyperechogenicity represents a pseudonodule with an area of more 'normal appearing' thyroid parenchyma (blue arrow).

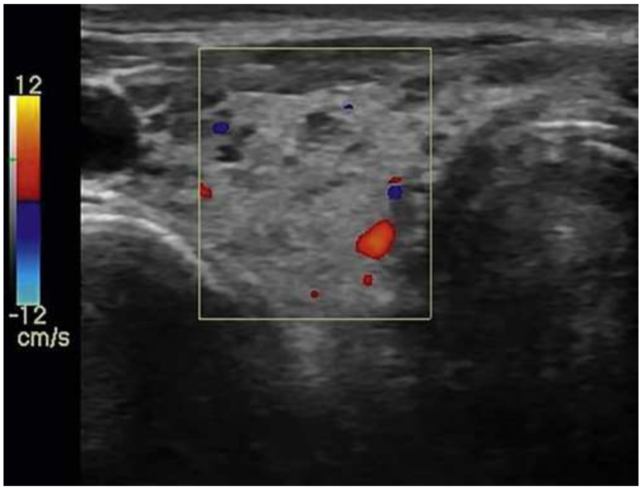

Fig. 69.e4 Image of Hashimoto's thyroiditis demonstrating reduced vascular flow.

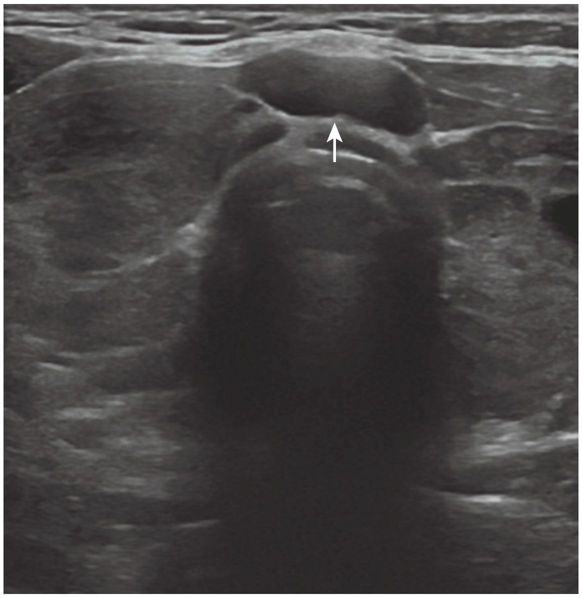

Fig. 69.e5 Diagnostic image of a thyroid ultrasound showing a hypertrophic delphian node in Hashimoto's thyroiditis (white arrow). Notice the hypoechogenicity of the thyroid gland and its similarity in color to the surrounding strap musculature.

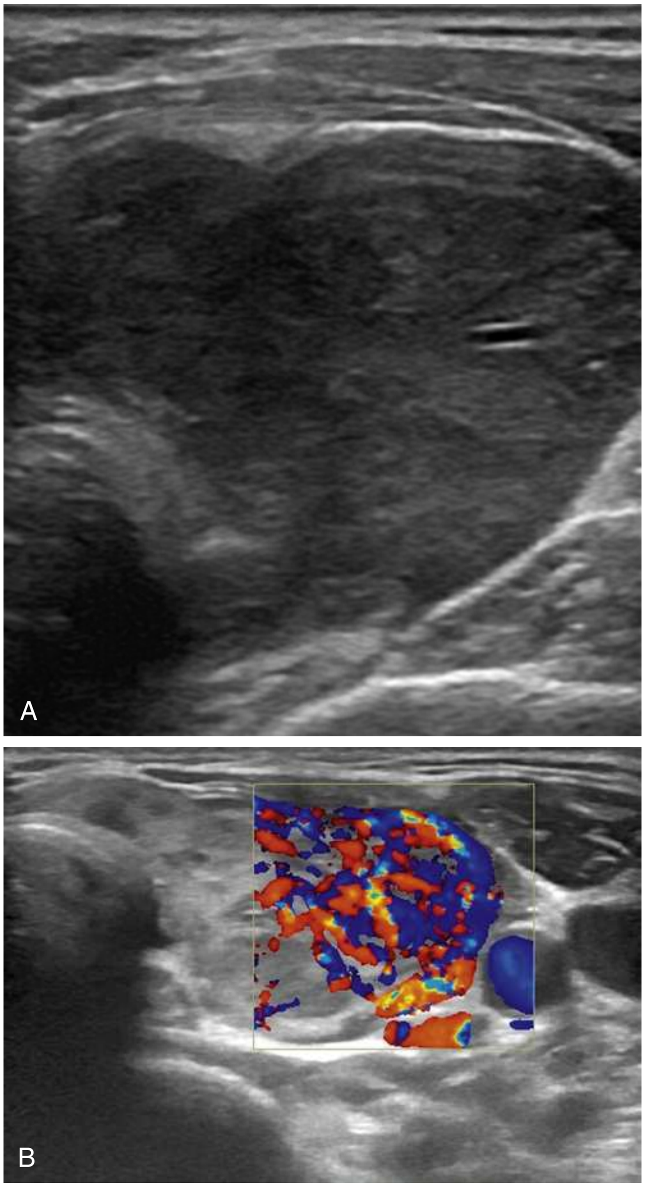

Fig. 69.3 A, Diagnostic image of a thyroid ultrasound showing lymphocytic thyroiditis involving the right lobe of the thyroid. Examination of the left lobe reveals marked enlargement and diffuse hypoechogenicity of the gland. Findings are consistent with primary thyroid lymphoma. B, Diagnostic image of a thyroid ultrasound demonstrating Graves disease. The gland is diffusely heterogeneous with markedly increased Doppler flow, also called thyroid inferno.

finding explains the bruit that often may be heard on physical examination and has been termed "thyroid inferno" when seen on US (see Fig. 69.3B).[11]

Thyroid nodules may be identified in up to 35% of patients with Graves disease when screening US is performed.[12] There is significant debate regarding whether nodules harbor an increased risk of malignancy in the setting of coexistent autoimmune thyroiditis.[13,14] Similar controversy exists regarding the prognostic significance of those nodules that are malignant; some studies suggest that the cancer is more aggressive with simultaneous Graves disease,[15] while others found no difference in clinical outcomes.[16] Although US identifies more nodules and cancers than palpation or scintigraphy,[17] screening US examination for all patients with Graves disease currently is not recommended.[18] The majority of cancers identified with screening sonography are subcentimeter tumors that have questionable clinical significance,[16] and the diagnostic evaluation can lead to increased morbidity if surgery is pursued.[19,20]

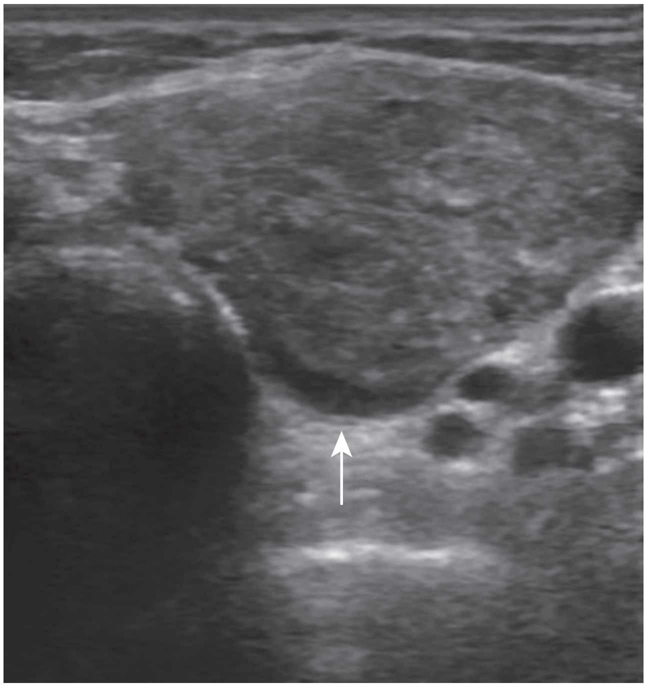

Fig. 69.4 **Diagnostic image of a thyroid ultrasound showing Graves disease.** The gland is diffusely hypoechoic and mildly enlarged with a prominent inferior thyroidal vein *(white arrow).*

PRIMARY THYROID LYMPHOMA

Primary thyroid lymphoma is a rare malignancy that represents less than 2% of all thyroid carcinomas.[21] It is more commonly seen in White women over the age of 60 years with a prior history of Hashimoto's thyroiditis.[22] Fortunately, most cases are diagnosed at an early stage and are associated with an excellent prognosis, but it is important to recognize the cardinal sonographic features of primary thyroid lymphoma, as a delay in diagnosis can negatively impact survival.[22] The clinical features are generally the first clue to the diagnosis; patients describe a several-week history of rapidly enlarging neck mass that may cause worsening dysphagia and a pressure sensation. Some patients also report "B symptoms" such as night sweats, fever, and weight loss.[23] Largely occurring in the setting of preexisting Hashimoto's thyroiditis, the US appearance can appear as an extreme manifestation of lymphocytic thyroiditis. A uniform, markedly hypoechoic gland with significant posterior acoustic enhancement that is significantly enlarged should increase the suspicion for primary thyroid lymphoma (Fig. 69.4). Depending on the stage and extent of disease, all or part of the gland may be involved. In higher-stage disease, the presence of enlarged locoregional adenopathy may also be seen.[24]

Subacute Thyroiditis

Subacute thyroiditis is a self-limited inflammatory disease that occurs in response to an antecedent viral illness. Patients present with acute neck pain and sudden-onset (often bilateral) thyromegaly, as well as fatigue and fever. In the acute phase, patients also may experience symptoms of thyrotoxicosis. Though the clinical presentation and significant anterior neck pain often is sufficiently diagnostic, US can aid in the distinction from other causes of thyrotoxicosis. The typical sonographic findings include focal, nonovoid areas of markedly

TABLE 69.1 American Thyroid Association Risk Stratification System

Risk Category	Description	Malignancy Risk	Threshold for FNA
High	Solid hypoechoic nodule or solid hypoechoic component in partially cystic nodule with one or more suspicious features*	>70%–90%	≥1 cm
Intermediate	Hypoechoic solid nodule with smooth margins lacking suspicious features**	10%–20%	≥1 cm
Low	Isoechoic or hyperechoic solid or partially cystic with eccentric solid areas lacking suspicious features**	5%–10%	≥1.5 cm
Very low	Spongiform or partially cystic without suspicious features	<3%	Consider ≥2 cm or observe
Benign	Purely cystic (no solid component)	<1%	No FNA

*Irregular margins (infiltrative, microlobulated), microcalcifications, taller-than-wide shape, rim calcifications with small extrusive soft tissue component, evidence of extrathyroidal extension.

**Microcalcifications, extrathyroidal extension, or taller-than-wide shape.

FNA, Fine-needle aspiration.

decreased echogenicity with significantly reduced vascularity (Fig. 69.e6A–E).[25] These poorly defined, hypoechoic areas may be seen in bilateral lobes and may be migratory if followed with serial examinations.[26] The inflammatory component typically produces enlargement of the gland.[27] Upon recovery from the disorder, there is characteristically complete resolution of sonographic abnormalities and return to normal thyroid volume.[28]

Sonographic Risk Stratification Systems

A number of sonographic risk stratification systems (SRSSs) have been developed to aid the clinician in assessing the need for fine-needle aspiration (FNA) and/or surveillance imaging upon identification of a thyroid nodule. The three main SRSSs presently in use are the American Thyroid Association (ATA), the American College of Radiology Thyroid Imaging Reporting and Data System (ACR-TIRADS), and the Korean Thyroid Imaging Reporting and Data System (K-TIRADS).[3,29]

American Thyroid Association Sonographic Risk Stratification System

Individual sonographic features have varying degrees of specificity for malignancy. The three individual features with the highest specificity for malignancy include a taller-than-wide shape (nonparallel orientation), presence of microcalcifications, and irregular (infiltrative, speculated, or microlobulated) margins; each of these features carries a median risk of malignancy of nearly 90%.[30] Independently, these high-risk features lack sufficient sensitivity, however, to effectively rule out malignancy in their absence. Furthermore, reliance on these individual features to assign malignancy risk is fraught with interobserver variability.[31] Consequently, the ATA system (Table 69.1) employs a pattern-based approach to the stratification of nodules.[3] This reliance on the assembly of sonographic features is more robust in terms of the reproducibility of the risk assessment.[32]

The ATA SRSS stratifies nodules into one of five risk categories. The benign category of nodules is comprised of simple cysts (Fig. 69.5). Because these lesions are benign, they do not require FNA for diagnostic purposes, regardless of nodule size. Therapeutic aspiration may be pursued if there are compressive symptoms or cosmetic concerns regarding their appearance. It is important to note, however, these lesions often reaccumulate fluid after such aspiration. The utility and interval for follow-up imaging of cystic nodules is unclear; if surveillance US is repeated, the interval should be greater than or equal to 24 months.[3]

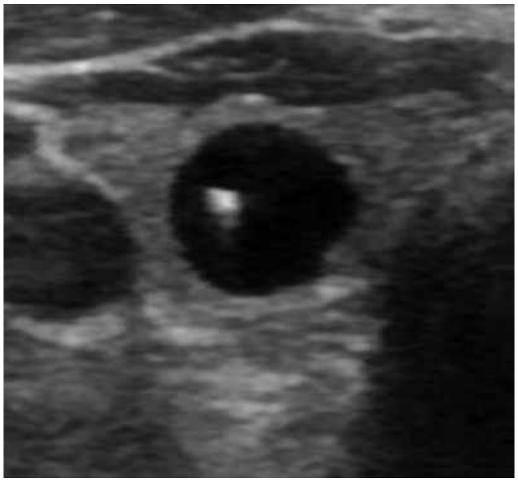

Fig. 69.5 **Diagnostic image of a thyroid ultrasound showing an American Thyroid Association benign nodule.** This nodule is a simple cyst.

The very low-risk suspicion nodules (Fig. 69.6) are comprised of spongiform nodules and partially cystic nodules without any suspicious US features (irregular margins, microcalcifications, taller-than-wide shape, or evidence of extrathyroidal extension). Spongiform nodules are defined as an isoechoic nodule with a microcystic aggregate that comprises greater than 50% of the lesion. The risk of malignancy for this category is less than 3%. Because of the low risk of malignancy for these nodules, a threshold of greater than or equal to 2 cm for FNA is recommended. Observation without FNA is also considered a reasonable option, depending on the clinical scenario. For those nodules that are aspirated and found to harbor benign cytology, the need for surveillance imaging is unclear, given the very low risk of missed malignancy. If US is repeated, the interval may be greater than or equal to 24 months.[3]

The ATA low-suspicion category includes isoechoic or hyperechoic solid nodules with no suspicious US features, or partially cystic nodules with an eccentric solid portion that lacks the suspicious features described above (Fig. 69.7).[3] Only 5% to 10% of these nodules are malignant, most of which are a follicular-patterned tumor (follicular carcinoma, follicular variant of papillary carcinoma, and noninvasive follicular tumor with papillary-like nuclear features [NIFTP]). Recognizing that metastatic spread is rare among follicular carcinomas under 2 cm, these lesions are recommended for aspiration at or above a size threshold of 1.5 cm. If aspirated and cytologically benign, these

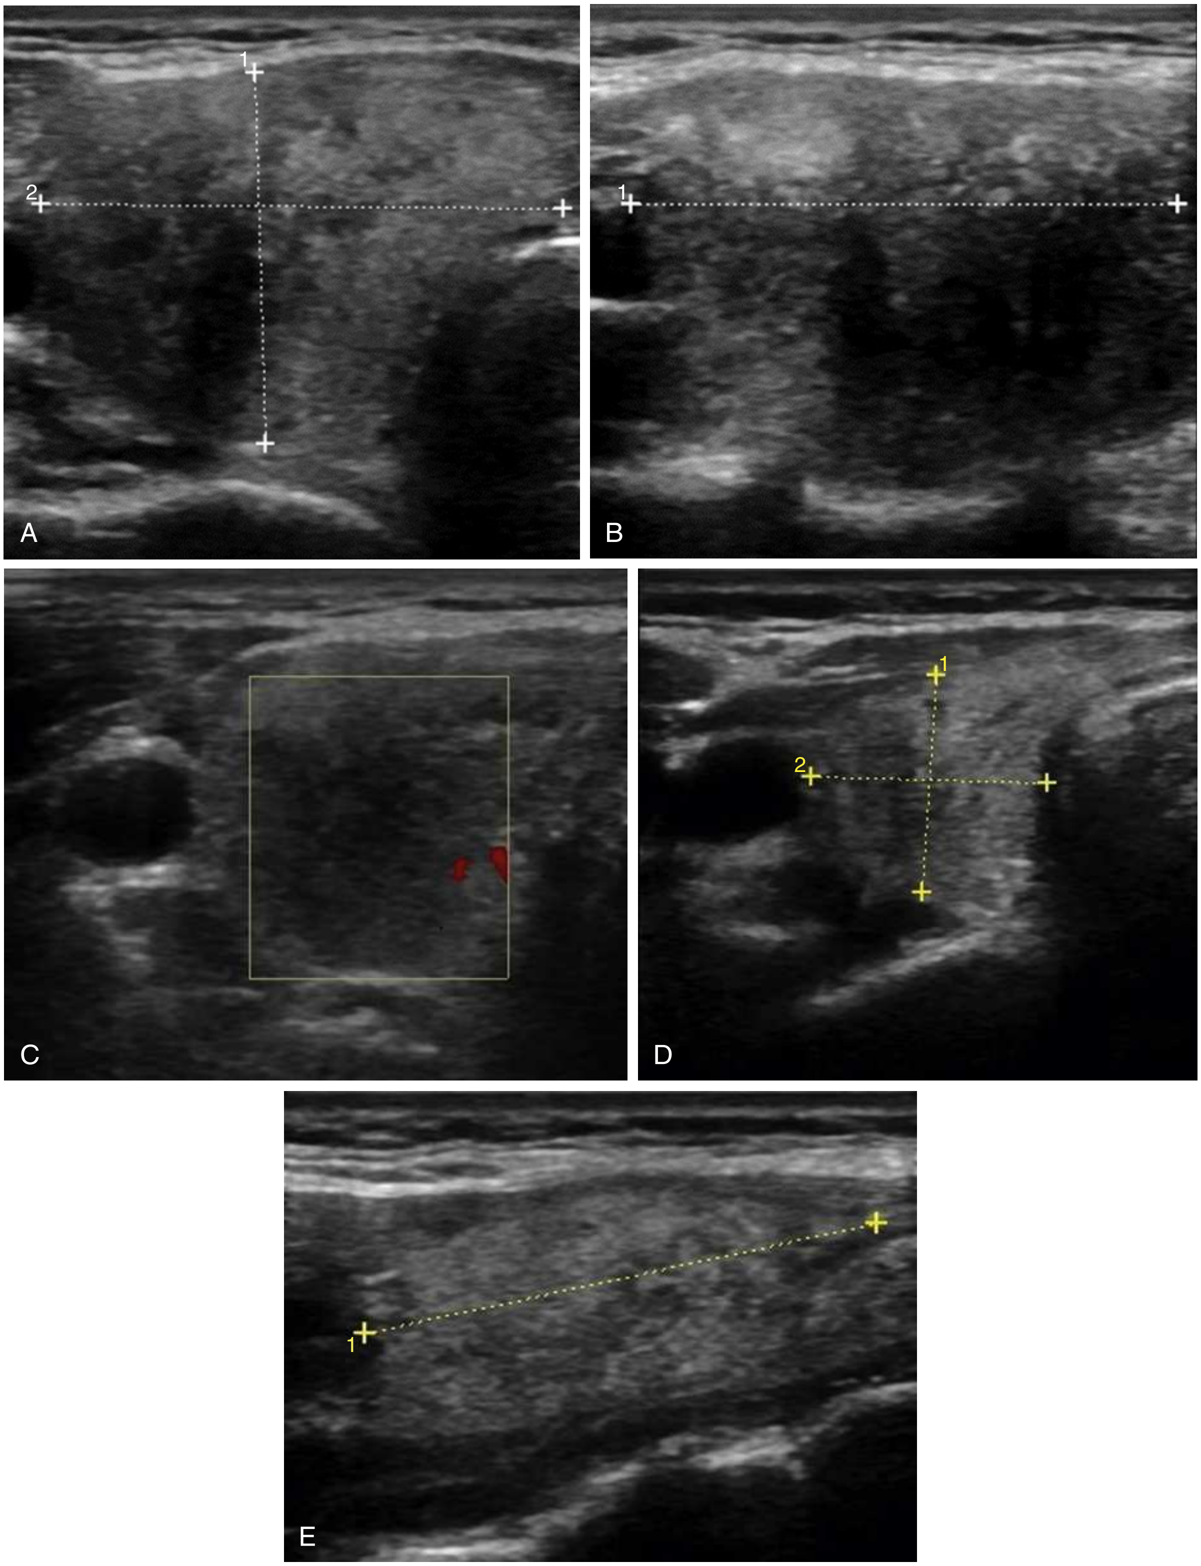

Fig. 69.e6 A, Diagnostic image of thyroid ultrasound showing the acute phase of subacute thyroiditis in the transverse view. The poorly defined markedly hypoechoic areas in the lower left corner of the image represent diffuse inflammation. Also note that the gland is significantly enlarged. B, Diagnostic image of a sagittal view of the thyroid ultrasound demonstrating the acute phase of subacute thyroiditis. The markedly hypoechoic area in the lower portion of the image represents the significant inflammatory component. C, Diagnostic image of color Doppler flow in DeQuervain's (subacute) thyroiditis. The significantly reduced Doppler flow is typical of subacute thyroiditis. D, Diagnostic image of thyroid ultrasound demonstrating the resolving phase of subacute thyroiditis. Repeat imaging of the same patient two months later reveals a significantly brighter echogenicity of the thyroid compared to image e4a. The gland is also returning to a more normal size as the inflammation wanes. E, Diagnostic image of thyroid ultrasound demonstrates the resolving phase of subacute thyroiditis.

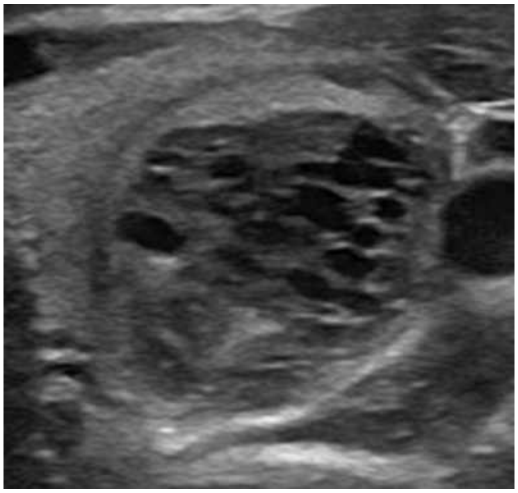

Fig. 69.6 **Diagnostic image of a thyroid ultrasound showing an American Thyroid Association very low–suspicion nodule.** This is an example of a spongiform nodule.

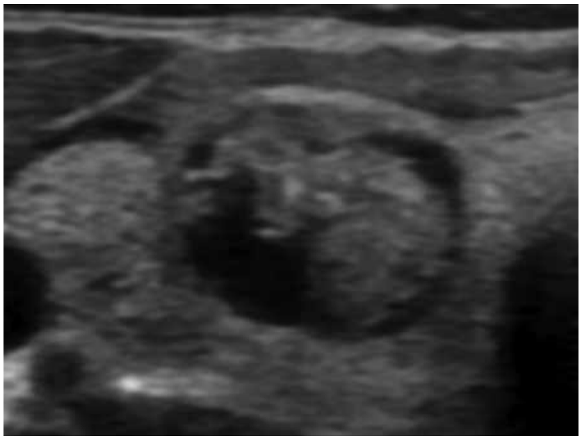

Fig. 69.7 **Diagnostic image of a thyroid ultrasound demonstrating an American Thyroid Association low-suspicion nodule.** This nodule is partially cystic with no suspicious ultrasound features.

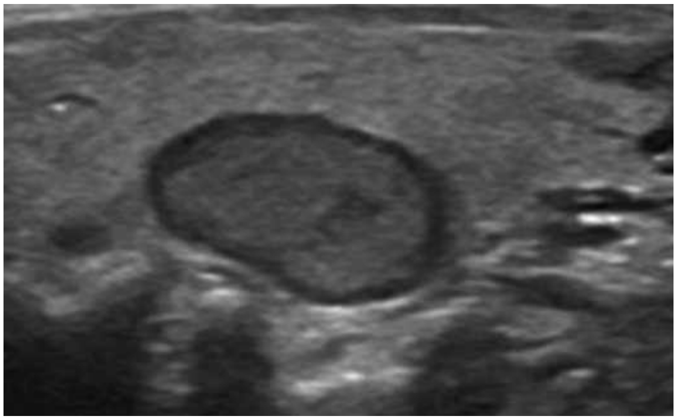

Fig. 69.8 **Diagnostic image of a thyroid ultrasound showing an American Thyroid Association intermediate-suspicion nodule.** This is a hypoechoic solid nodule with regular margins and lacking suspicious features.

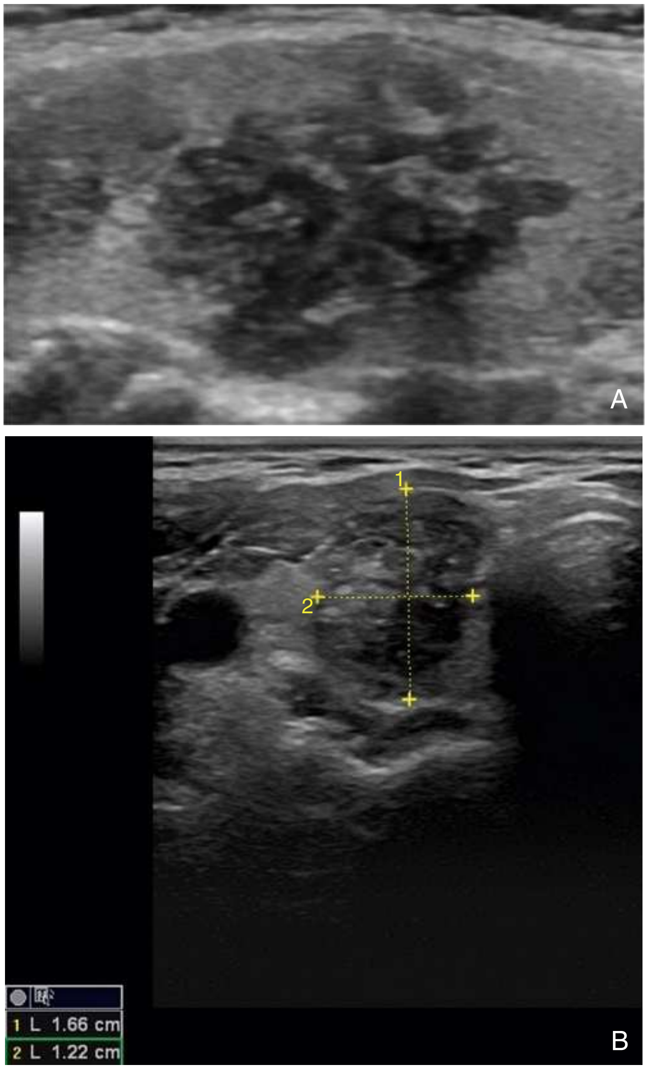

Fig. 69.9 **A,** Diagnostic image of a thyroid ultrasound demonstrating an American Thyroid Association high-suspicion nodule. This image shows irregular or infiltrative margins in a markedly hypoechoic nodule. **B,** Diagnostic image of a thyroid ultrasound showing a hypoechoic solid nodule with taller-than-wide shape.

nodules are recommended for surveillance imaging at 12 to 24 months after FNA.[3]

ATA intermediate-suspicion nodules are hypoechoic and solid with a regular margin, but lacking suspicious US features (Fig. 69.8). While this pattern has the highest sensitivity for detecting malignancy, it lacks specificity; approximately 10% to 20% of these nodules are malignant.[3] The threshold for aspiration is 1 cm. Nodules with a benign FNA are recommended for repeat US at 12 to 24 months.[3]

The ATA high-suspicion category includes solid, hypoechoic nodules (or cystic nodules with a hypoechoic solid component) and one or more suspicious US features, including microcalcifications, taller-than-wide shape, evidence of extrathyroidal extension (ETE), irregular margins, or a disrupted rim calcification with extrusive hypoechoic soft tissue component (Figs. 69.9A and B and 69.e7A–C). This is the category with the highest specificity, and identification of one of these types of nodules has a risk of malignancy of 70% to 90%. Nodules with this pattern measuring 1 cm or more are recommended for consideration of FNA.[3] For those highly suspicious nodules measuring less than 1 cm, lacking evidence of ETE, suspicious locoregional nodes, or concern for distant metastatic disease, FNA or observation may be considered based on patient age and clinical scenario. If a highly suspicious nodule is aspirated and found to have benign cytology, consideration should be given to repeat the FNA within 12 months, as the risk of a false-negative result is higher in this population.[33] Nodules with a high-suspicion pattern that do not meet the threshold for FNA should be considered for repeat surveillance US in 6 to 12 months.[3]

One important limitation to this pattern-based approach is that not all types of nodules are captured with this system. Approximately 4% to 18% of nodules are nonclassifiable by the ATA system.[34,35] In particular, isoechoic nodules with a suspicious US feature are not assessable with the current system (Figs. 69.10 and 69.e8A–C). The malignancy risk associated with these types of nodules is unclear, with widely disparate rates reported between 9% and 68%,[36-39] though most report the malignancy rate on the lower end of that range.

Korean Thyroid Imaging Reporting and Data System

The K-TIRADS (Table 69.2), initially created in 2011[40] and revised in 2016,[41] is similar to the ATA system in its size thresholds for FNA but differs in that it employs a four-tiered stratification. Additionally, K-TIRADS recommends FNA for some high-risk nodules measuring 5 mm or more (in contrast to the 1-cm threshold for all other systems) for certain high-risk patients.

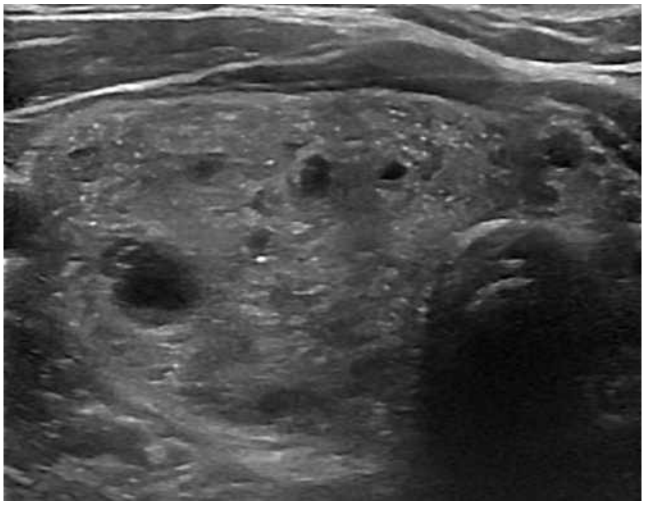

Fig. 69.10 Diagnostic image of a thyroid ultrasound showing an isoechoic mixed composition nodule with microcalcifications.

K-TIRADS emphasizes nodule composition followed by echogenicity for assignment of malignancy risk. The algorithm stratifies solid hypoechoic nodules as the two highest-risk tiers. The presence of sonographically suspicious features (microcalcification, nonparallel orientation, spiculated/lobulated margins) elevates a nodule from K-TIRADS 4 to the highest risk category, K-TIRADS 5. Partially cystic or iso/hyperechoic solid nodules with a suspicious feature are considered intermediate-suspicion or K-TIRADS 4, whereas the absence of a suspicious feature is considered low-suspicion, or K-TIRADS 3. Those nodules that are pure cysts, spongiform, or partially cystic with comet-tail artifact (Fig. 69.e9) are considered benign, or K-TIRADS 2.[41]

The K-TIRADS 3 and 4 nodules that are biopsied and found to have benign cytology are recommended for repeat imaging at 12 to 24 months. K-TIRADS 5 nodules with benign cytology are recommended for repeat FNA at 6 to 12 months of follow-up, in recognition of the high rate of false-negative cytology with a suspicious US appearance and benign cytology.[41]

American College of Radiology Thyroid Imaging Reporting and Data System

A more recent system endorsed by the American College of Radiology utilizes a summation of scores associated with individual features to derive a malignancy risk[29] (Table 69.3). This ACR-TIRADS system specifically examines five nodule features: composition, echogenicity, shape, margin, and echogenic foci. Within each category, the types of findings are assigned a score; higher values are associated with increasing malignancy risk.[29]

The ACR-TIRADS is composed of five levels of thyroid nodules. Those nodules that fall into the TR1 (0 points) and TR2 (2 points) categories are considered benign and not suspicious, respectively, and as such require neither FNA nor follow-up. Those nodules with 3 points are deemed “mildly suspicious,” or TR3; FNA is recommended if the nodule measures 2.5 cm or more. Nodules of this class that measure 1.5 cm or more are advocated for follow-up. Nodules with an aggregate of 4 to 6 points are considered “moderately suspicious,” or TR4, and FNA is advised if greater than or equal to 1.5 cm, with follow-up for those greater than or equal to 1 cm. Nodules that have accrued 7 or more points are regarded as “highly suspicious,” or TR5. FNA is recommended for those measuring greater than or equal to 1 cm, while follow-up is encouraged for those measuring 5 mm or more. Similar to the other two SRSSs, routine FNA of highly suspicious nodules measuring 5 mm or more is not recommended. However, in certain circumstances, FNA may be indicated.[29]

The ACR-TIRADS system also provides a framework for surveillance of nodules, both those meeting criteria for FNA and those that do not. For TR 5 nodules, the committee recommends annual US exam

TABLE 69.2 Korean Thyroid Imaging Reporting and Data System Risk Stratification System

Risk Category	Description	Malignancy Risk	Threshold for FNA
High	Solid, hypoechoic *with* any suspicious feature*	>60%	≥1 cm; (>0.5 cm selective^)
Intermediate	Solid hypoechoic *without* suspicious features OR Partially cystic or iso/hyperechoic *with* any suspicious feature*	15%–50%	≥1 cm
Low	Partially cystic or iso/hyperechoic *without* any suspicious feature*	3%–15%	≥1.5 cm
Benign	Spongiform OR Partially cystic with comet-tail artifact OR Pure cyst	<3% <1%	≥2 cm N/A

*Suspicious features include: microcalcification, nonparallel orientation (taller-than-wide), or spiculated/microlobulated margin.

^FNA of nodules >5 mm may be performed for those patients with risk factors requiring immediate surgery, such as those with evidence of extrathyroidal extension, nodal metastases, or distant metastases. Additionally, those nodules with evidence of invasion into the trachea or recurrent laryngeal nerve may be biopsied.

FNA, Fine-needle aspiration.

C, Diagnostic image of a thyroid ultrasound showing a solid nodule with heterogeneous echogenicity.

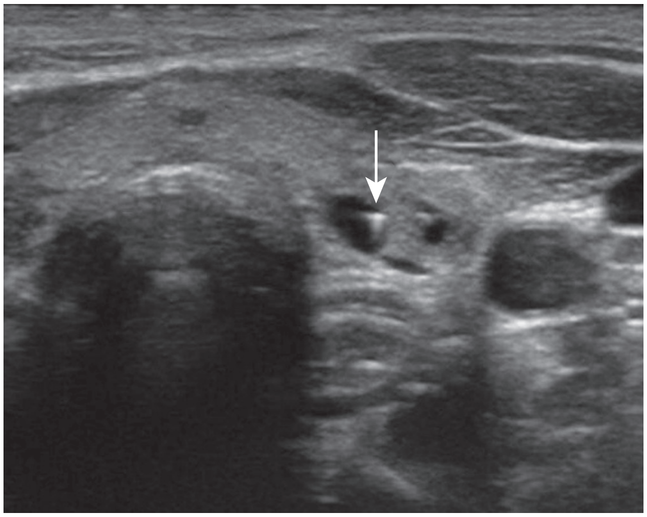

Fig. 69.e9 Diagnostic image of thyroid ultrasound showing a comet-tail sign (white arrow) or punctate echogenic focus with a vee-shaped posterior tail. These findings are reassuring in a purely cystic nodule.

TABLE 69.3 American College of Radiology Thyroid Imaging Reporting and Data System

Nodule features and associated points for each characteristic.

Composition	*Echogenicity*	*Shape*	*Margin*	*Echogenic Foci*
Cystic 0	Anechoic 0	Wider than tall 0	Smooth 0	None 0
Spongiform 0	Hyper-/isoechoic 1	Taller than wide 3	Ill-defined 0	Comet tails 0
Mixed 1	Hypoechoic 2		Irregular 2	Macrocalcifications 1
Solid 2	Markedly hypoechoic 3		ETE 3	Peripheral/rim 2
				Punctate 3

ACR-TIRADS scores and FNA thresholds

Score	*0*	*2*	*3*	*4–6*	*≥7*
TIRADS Class	TR1	TR2	TR3	TR4	TR5
Description	Benign	Not suspicious	Mildly suspicious	Moderately suspicious	Highly suspicious
FNA Threshold	Not recommended	Not recommended	≥2.5 cm	≥1.5 cm	≥1 cm

FNA, Fine-needle aspiration; *ACR,* American College of Radiology; *TIRADS,* Thyroid Imaging Reporting and Data System.

every year for up to 5 years. Those nodules categorized as TR4 should be scanned at years 1, 2, 3, and 5, whereas TR3 lesions may be imaged at 1, 3, and 5 years of follow-up. This committee proposes that imaging can stop at 5 years if there is no change in size, as a lack of growth over that length of time is highly consistent with a benign-behaving neoplasm. Furthermore, they recommend that if a nodule's TIRADS level increases during follow-up, repeat imaging in 12 months is warranted, regardless of the initial grade.[29]

The major limitation of ACR-TIRADS is the need to memorize a number of features and their associated scores. The attendant interobserver variability associated with each feature further constrains the reliability of this system for accurately characterizing malignancy risk. Another criticism of ACR-TIRADS is that using it can become time-consuming, particularly in the setting of having to categorize multiple nodules; assessing nodules with a pattern-based system is significantly quicker.

Diagnostic Performance of Sonographic Risk Stratification Systems

While each of these systems have their individual limitations and strengths, their performance for distinguishing benign from malignant nodules in prospective and retrospective analyses is very similar. Generally, the ATA and K-TIRADS have a high sensitivity for detecting malignancy but do so at the cost of a lower specificity. Consequently, these two systems are associated with a higher "unnecessary biopsy rate" or recommend more biopsies of what are ultimately benign nodules.[42] In contrast, the ACR-TIRADS typically has a higher specificity and lower sensitivity than the ATA and K-TIRADS; the unnecessary biopsy rate for ACR-TIRADS is accordingly lower.[42]

An important caveat to all SRSSs is that they are designed to identify papillary thyroid carcinoma. The sonographically suspicious features of taller-than-wide shape, microcalcifications, and infiltrative margins are more specific for papillary carcinomas.[43] In contrast, follicular-patterned tumors generally appear as solid, isoechoic, or mildly hypoechoic nodules with a regular oval shape and lacking microcalcifications.[43,44] Consequently, the papillary thyroid carcinomas tend to be represented by the "high-risk" lesions on all SRSSs, whereas the follicular tumors are represented in the "low-risk" and "intermediate-risk" categories. It is also noteworthy that nearly all studies examining the performance of various SRSSs include very limited numbers of follicular-patterned tumors in their cohort of nodules. While the decreased prevalence of follicular carcinoma partly contributes to this lack of representation, many of the studies also exclude nodules with indeterminate cytology, which disproportionately eliminates follicular tumors.[45] As a result, it is unclear how well these SRSSs perform with identification of malignancy in follicular-patterned tumors.[45]

KEY POINTS

- Though each of the three main sonographic risk stratification systems have individual strengths and weaknesses, they perform similarly to categorize the malignancy risk of thyroid nodules.

Specialized Sonographic Techniques

Contrast-Enhanced Ultrasonography. Contrast-enhanced ultrasonography (CEUS) is a technique that is helpful to uncover tissue microvascularization, a critical component of neoplastic growth. Microbubbles, composed of a shell with a gas core, are employed as contrast agents and act as echo enhancers to improve visualization of tissue microperfusion. These 1- to 10-µm microbubbles are capable of passing through capillary vessels, allowing for improved characterization of tumor vascularity.

These microbubbles resonate in response to a specific transmitted acoustic wave frequency, which is dictated by the radius of the microbubble. Those agents used in thyroid applications respond to the US frequencies used in evaluation of thyroid tissues, 7 to 15 MHz.[46] The contrast agent is then detected by the US device because it has acoustical characteristics that are different from the surrounding soft tissues. The difference in acoustic impedance compared with the surrounding tissues results in a mismatch with reflection of the US wave back to the probe, which enhances the imaging characteristics and leads to improved detection of subtle features.[46]

The contrast agent is typically powdered and requires reconstitution in normal saline. It is administered intravenously in the antecubital fossa for each CEUS examination. The microbubble perfusions can be seen within a few seconds in the targeted nodule and typically can be observed for 2 minutes or less. After injection of the contrast agent, the US machine is switched to contrast mode and directed to the region of interest, with the focal zone placed at the posterior edge of the nodule (Fig. e69.10). Because of the short interval that the microbubbles remain within the thyroid nodule, it is important to record cine-loops after the administration of contrast for later, more careful inspection of the nodule.

Being rich in microvessels, the normal thyroid parenchyma demonstrates a rapid, uniform enhancement after injection of the contrast. Nodules, on the other hand, exhibit a different vascular structure and consequently stand out from the surrounding normal tissue. The

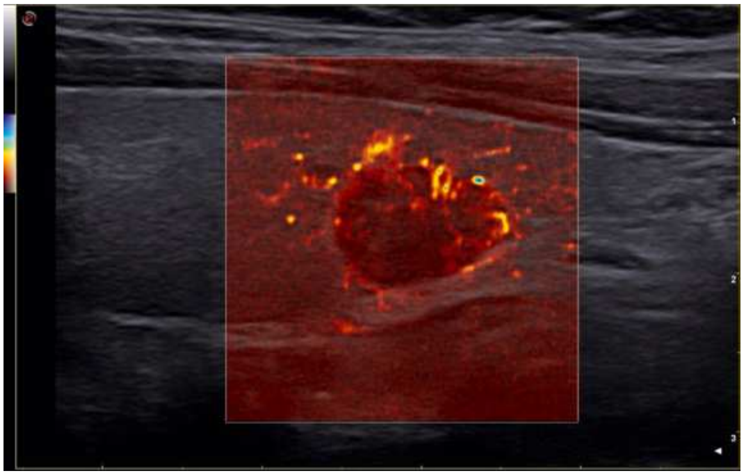

Fig. 69.e10 Contrasted ultrasonography

resultant images of the nodules are then qualitatively analyzed by their vascularization features.

Quantitative analysis also may be performed upon completion of the image acquisition. Using the quantification software, the operator manually distinguishes a region of interest and automatically calculates various parameters including: peak intensity, time to peak, mean transit time, and total volume of blood in the region of interest.[47] The role that these features play in distinguishing benign and malignant neoplasms is still under investigation, however.

Elastography. On palpation examination, the firmness of a thyroid nodule is assessed; increasing hardness of the tissue is associated with greater concern for the possibility of malignancy. US elastography (USE) is a bedside tool that can be used to objectively measure this tissue stiffness. This technology may aid in the assessment of malignancy risk of thyroid nodules, with stiffer nodules having a higher likelihood of harboring a cancer. While utilizing USE requires specific software and a special probe, it allows for assessment of nonpalpable nodules. The measure of tissue elasticity is compared with that of adjacent musculature for a quantitative assessment. There are two main forms of applied force: external compression of the probe applied by the user or shear wave generated by the US machine.

The external compression form of elastography (also known as strain USE [SUSE]) is manually performed by pressing the probe into the skin of the patient, generating tissue strain perpendicular to the skin surface. The nodule and surrounding parenchyma are highlighted with a box on the screen. US images are taken before and after the tissue compression. Software then measures the degree of tissue displacement with the pressure; the degree of stiffness is inversely proportional to the amount of tissue deformation. The data are then processed to create a corresponding color scale that is superimposed on the US image. The colors range from blue (which has the lowest degree of elasticity and the highest risk of malignancy) to green (intermediate elasticity) to red (corresponding to the highest degree of elasticity and lowest risk of malignancy) (Fig. 69.e11). SUSE is older technology that is prone to bias; its utility is limited by operator experience and tissue depth.

The newer technology, shear wave elastography (SWE), creates particle motion tangential to the skin surface. Utilizing an acoustic radiation force pulse generated from the probe, shear waves that are perpendicular to the US beam cause transient displacement of the tissues. The distribution of shear-wave velocities is directly related to the tissue's elastic properties, as shear waves propagate faster through stiffer tissue. The US probe detects these changes and translates the data into an image that conveys the degree of tissue elasticity. The benefit of this technology is that it is independent of user experience.

There are important limitations of elastography that likely have contributed to its failure to achieve widespread adoption into clinical practice. USE cannot be used in nodules with calcifications, as their hardness will artificially reduce the tissue strain. Similarly, the presence of a cystic component in a nodule precludes the use of this technology, as it will falsely elevate the compressibility of the nodule tissue. Many studies also exclude those patients with Hashimoto's thyroiditis due to the potential for the lymphocytic infiltrate and tissue fibrosis to influence the tissue compressibility.

It is unclear how location of the nodules impacts the performance of SUSE, particularly those that are posteriorly located or in the isthmus. The nodules in the isthmus or near the trachea may not be assessed with this technology due to the interference produced by the tracheal cartilage. One recent, small, retrospective analysis[48] examined the question of nodule depth on performance of SUSE. The authors found that, while the depth of the nodule did not impact the ability to measure tissue stiffness, proximity to the carotid did influence the accuracy. The elasticity contrast index was underestimated for those nodules located within 15 mm of the carotid.[48] Suspicious nodules are associated with a higher elasticity contrast index, and underestimation of this value may result in a false reduction of the malignancy risk. This "geographic" limitation is of particular significance in women, as their thyroid lobes tend to be smaller, measuring between 15 and 20 mm in the transverse direction. A smaller lobe positions the majority of nodules within those regions where the tissue strain may be misregistered.

Initial analyses of the performance of elastography revealed that the technology had remarkably high sensitivity and specificity for distinguishing benign from malignant nodules.[49,50] While useful for a proof of concept, subsequent studies inclusive of a more diverse nodule population were unable to replicate such a highly discerning performance.[51]

There are noteworthy methodologic flaws in many of the studies examining the utility of USE. Due to the retrospective nature and small sample size of most of the studies, there is the significant potential for selection bias. Many of the analyses examined patients with a solitary nodule, further limiting the diagnostic relevance of this technology in the general population, particularly those with multinodular goiter.[51] Additionally, many of the early studies excluded nodules with indeterminate cytology from the analysis of the performance of USE. However, the ability to discern the malignant potential of nodules with indeterminate cytology would be an ideal utility for this technology. Nodules with a suspicious appearance on traditional gray-scale sonography do not require further risk stratification, as the specificity of these findings is already satisfactorily elevated.[3] Instead, it is nodules with an intermediate- or low-risk appearance on gray-scale US that would benefit from the augmented diagnostic accuracy of identifying the few malignancies within this class of nodules. Those nodules that are malignant in these low- and intermediate-risk sonographic categories tend to represent follicular-patterned tumors such as follicular carcinoma, follicular variant of papillary thyroid carcinoma, or NIFTP. Consequently, exclusion of nodules with indeterminate cytology not only limits the utility of this testing, but also provides an incomplete picture of its performance. Unfortunately, those few analyses that include indeterminate cytology provide conflicting results regarding how well this technology performs in this population,[52-55] likely owing to small sample sizes and potential selection bias. Nevertheless, a recent metaanalysis that included 1734 nodules did show a modest diagnostic performance with USE in indeterminate nodules; the pooled sensitivity and specificity were 76.6% and 86.7%, respectively.[56] An important limitation of this particular study is that SUSE and SWE were combined into one analysis. Thus, it remains unclear how these individual technologies perform for the malignancy risk prediction with indeterminate nodules. Nonetheless, in spite of the abovementioned concerns, the potential of this technology to play a role in the assessment of nodules in conjunction with the gray-scale sonographic risk stratification to help stratify malignancy risk remains intriguing.[57-60]

Computer-Aided Diagnosis Systems. One of the major concerns regarding traditional gray-scale US is that its diagnostic performance relies heavily on the expertise of the interpreting sonographer.[61] The sonographic features used to describe nodules are fraught with interobserver variability in reporting.[62,63] In areas where proficiency in US interpretation is lacking, there is a need for technology that will deliver diagnostic accuracy using sonographic analysis in a timely fashion. Artificial intelligence is being increasingly investigated as a possible adjunctive tool to assist in the decision-making or to provide a second opinion for the diagnosis of malignant nodules with operators who have less experience using US.[64]

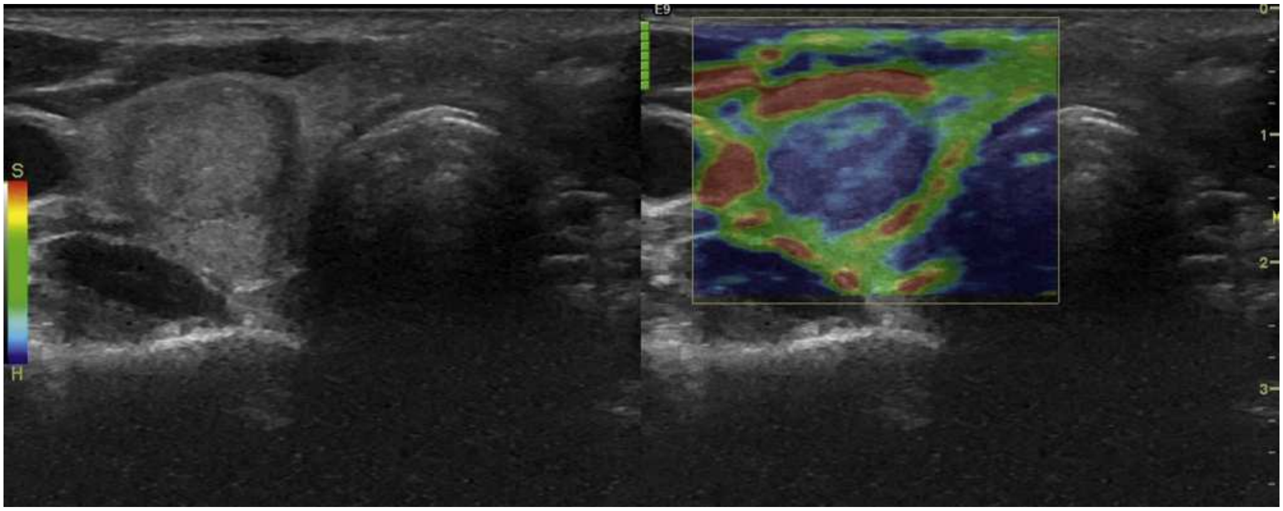

Fig. 69.e11 B-mode US and elastography image of a high-risk thyroid nodule. The blue regions demonstrate areas of decreased compressibility.

There are two main types of machine learning methods: the classic machine learning (CML) method and the deep learning (DL) method. The CML model utilizes features defined by human experts; it merely simulates the diagnostic strategy of radiologists. Those sonographic images of nodules with known histologic diagnoses of malignancy or benignity are fed into the system by the radiologist to "train" the computer with these associations. Consequently, the CML model is limited in its ability to transcend the imperfections of its human teachers. The DL model overcomes this important obstacle by decreasing subjectivity during the training process: it allows computational models, composed of multiple processing layers, to learn representations of data with compound levels of abstraction.[65] Specifically, DL uses numerous levels of training with representative images. Each layer of learning adds a level of complexity to aid in the discriminatory power of the machine. The key aspect of this learning method is that it is independent of human input; the learning is solely derived from the data or raw images entered into the system.[65]

A recent metaanalysis examined the diagnostic performance of the two computer-aided diagnosis (CAD) systems and compared their performance with that of experienced radiologists. In an analysis of six separate studies, the pooled sensitivity and specificity were 86% and 85%, respectively, for CML-based CAD.[66] The DL-based CAD systems performed similarly, with a pooled sensitivity and specificity of 89% and 84%, respectively.[66] The pooled sensitivity, specificity, area under the curve, and diagnostic odds ratio were comparable between the two CAD systems and the radiologists' interpretations.[66]

Given the rising incidence of thyroid cancer, much of which is due to increased detection of subclinical disease,[67] a tool that can rapidly and accurately sort through nodules with limited intervention would be of great value. Machine-based learning offers an attractive option for the rapid analysis of incidentally-detected nodules to help radiologists identify high-risk lesions and potentially prevent unnecessary FNA of low-risk nodules.

CAD technology has only recently become available outside of a research setting; there is one company that has created software that can be integrated into a US platform.[68] However, as yet, these tools are not ready for clinical practice. The existing studies are designed to prove technical feasibility, but real-world clinical performance has not yet been demonstrated.[68] Multicenter, prospective trials and observational outcome studies are needed to demonstrate efficacy.[68,69] Until such studies are performed, widespread adoption of this technology into clinical practice seems less likely.

SCINTIGRAPHY

Radionuclide scintigraphy was once the mainstay of evaluation of thyroid disorders. With the advent of bedside US to stratify malignancy risk in thyroid nodules, routine scintigraphic analysis of the thyroid has declined. However, this imaging technique remains the only methodology to evaluate the functional status of a thyroid nodule, and it remains a useful tool for the distinction of Graves disease from subacute and silent thyroiditis. Furthermore, it is an important component of the evaluation of select cases of congenital hypothyroidism. The use of nuclear scintigraphy for the evaluation and treatment of thyroid cancer is discussed in Chapter 78.

Radioiodine tests are composed of two distinct parts: the planar imaging and the measurement of the percent uptake of iodine. One or both components of radionuclide testing may be performed for determination of the underlying thyroid disorder. The radiotracer is given to the patient either intravenously or orally. The timing of the scan is dependent on the route of administration and the type of tracer utilized. The patient is placed on an examination table, and a gamma camera takes images of the thyroid region from three different angles: anterior, posterior, and oblique.

TABLE 69.4 Drugs Impacting Uptake of Tracer in the Thyroid

Impact	Agent
Decreased Uptake	Amiodarone
	Methimazole
	Perchlorate
	Propylthiouracil
	High dose salicylates
	Sulfonamides
	Thiocyanate
	Triiodothyronine (T3)
	Thyroxine (T4)
	Iodine-containing ointments
	Kelp
	Cough medicine and vitamins containing iodine
	Iodinated contrast agents
Increased Uptake	Lithium

The patient should be carefully prepared for the test, including a thorough review of medications and recent imaging studies. In patients who are already being treated for hyperthyroidism it is important to hold thionamide therapy for at least 5 days prior to the scan to ensure accurate results. A number of other drugs can falsely alter the uptake of tracer within the thyroid (Table 69.4). In the setting of iodine deficiency there can be falsely increased uptake of radiotracer. The administration of iodinated contrast with computed tomography (CT) can falsely lower the uptake of radioiodine tracer. Chronic renal failure can impair iodine clearance and lower radioiodine uptake. Also, increased ingestion of goitrogenic foods such as cabbage and turnips may artificially lower uptake of the tracer.

Radionuclide imaging is absolutely contraindicated in pregnancy; radiation exposure from the scan is harmful to the developing fetus. A negative pregnancy test should be obtained prior to performing this testing for all females with reproductive potential. In addition, because radioactive iodine is secreted in breast milk, lactating women should not undergo nuclear scintigraphy. If it is critical to perform scintigraphy, lactating women should be instructed to pump and discard the breastmilk for 5 days after the ^{123}I administration.

Thyroid Nodules

Thyroid scintigraphy is most commonly performed for evaluation of the functional status of a nodule. Nodules are described based on the pattern of uptake of the radiotracer compared with the surrounding thyroid parenchyma. Nodules that are hyperfunctioning are classified as "hot," while hypofunctioning lesions are termed "cold" (Fig. 69.11). Those nodules that demonstrate similar activity to the surrounding thyroid parenchyma are defined as "warm" or indeterminate. Hot nodules are almost exclusively benign; they do not routinely require FNA interrogation.[3] In contrast, cold or warm nodules may harbor a malignancy, and consequently FNA may be warranted based on their sonographic appearance.[3]

The two main radionuclides employed for the evaluation of thyroid nodules are ^{123}I (radioiodine) and ^{99m}TcO4^{-} (pertechnetate). The ^{123}I is both concentrated and organified within the thyroid, whereas ^{99m}TcO4^{-} is only concentrated in the gland, without organification. This

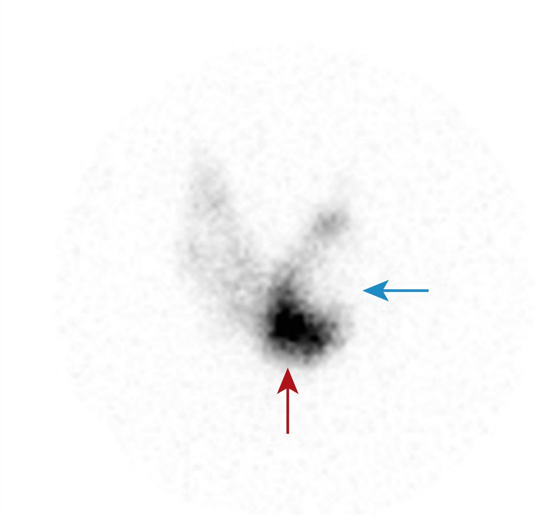

Fig. 69.11 Diagnostic image of ^{123}I scintigraphy demonstrating a hot nodule *(red arrow)* with an adjacent cold nodule *(blue arrow)*.

distinction is important for the evaluation of nodules. Approximately 5% of thyroid cancers concentrate pertechnetate but not radioiodine.[70] These nodules may falsely appear as functional on pertechnetate scans, while they actually are nonfunctioning on radioiodine scans. Consequently, the ATA guidelines preferentially recommend ^{123}I over $^{99m}TcO4^{-}$ for scintigraphic scanning.

There are benefits and disadvantages to the use of each of the tracers. The use of technetium exposes the patient to less radiation, but because it is not organified, it does not allow for the measurement of uptake. Because technetium is not retained within thyroid tissue, this type of scintigraphy must be performed within 20 to 30 minutes after injection of the tracer, providing rapid, convenient results for the patient. An additional benefit of technetium is that it is less expensive and more readily available than iodine isotopes. Radioiodine, on the other hand, allows for better image quality and resolution, particularly when thyroid uptake is low. Radioiodine is metabolized identically to naturally occurring iodine, and it is incorporated into thyroglobulin for storage in thyroid follicles. The emission of gamma rays from the ^{123}I allows for the imaging of the thyroid several hours after ingestion or infusion of this tracer. Measurements of uptake are performed 1 hour after intravenous injection or at 4 and 24 hours after oral administration. The timing of varying degrees of intrathyroidal uptake is then utilized to further differentiate the underlying pathophysiologic process. The radioiodine scans are more inconvenient to the patients; the delayed images over 24 hours require patients to return to the imaging center for multiple scans. Additionally, ^{123}I is a more expensive tracer, and at times it can be difficult to obtain the tracer due to interruptions in the supply chain.

A thyroid radionuclide scan is not essential for the investigation of all thyroid nodules. The initial step in the evaluation of sonographically-confirmed thyroid nodules involves measurement of a serum thyroid-stimulating hormone (TSH). If the TSH is low, a scintigraphic scan is beneficial to ascertain the functional status of the nodule. Because the malignancy risk is generally accepted to be extremely low in hot nodules, further analysis with FNA is largely unnecessary. On the other hand, nodules that are deemed warm or cold may require further investigation with FNA to rule out malignancy. Conversely, for patients with a normal or elevated TSH level, the likelihood of identifying a functional nodule on scintiscanning is very low. As such, a radionuclide study is generally not recommended in this setting.[3] Nevertheless, in iodine-deficient regions, TSH may remain unsuppressed even in the presence of nodule autonomy due the low production rates of thyroid hormone in the iodine-depleted gland. Indeed, a metaanalysis of eight studies evaluating scintigraphy revealed that up to 50% of autonomous nodules had a normal TSH.[71] Thus, it may be beneficial to perform scintigraphy in the setting of a nodule or multinodular goiter with a low-normal TSH in an area of iodine deficiency, as the risk of autonomy may be high in this population.[4]

It is important for clinicians to be familiar with the limitations of nuclear scintigraphy. The resolution of radionuclide scanning is very poor in comparison to ultrasonography. Cold nodules measuring less than 1 cm are very likely to be missed on scintigraphy. Furthermore, posteriorly located nodules may be difficult to characterize. Overlying normal thyroid tissue could distort the images and impart a warm appearance to a posterior, nonfunctioning nodule. Additionally, in cases of a multinodular goiter with nodules of varying functionality, it can be difficult to distinguish which lesion has corresponding activity, particularly in the event of overlapping nodules. In these settings, it is important to carefully perform scintigraphic imaging at multiple angles and closely correlate the findings with the US exam. Finally, concentration of the tracer by the esophagus can mimic ectopic thyroid tissue. If this situation is suspected, it is important to acquire additional images after swallowing water to determine if the tracer has cleared.

Diffuse Thyroid Disorders

Uptake scintigraphy is helpful for distinguishing the causes of thyrotoxicosis from diffuse thyroid disorders. Abnormal uptake values are described as either high or low. Those conditions with high or normal uptake are indicative of synthesis of thyroid hormone. In contrast, those conditions with low or absent uptake may be seen due to either destruction/inflammation of the thyroid gland with release of preformed hormone into the circulation or due to an external source of thyroid hormone (exogenous thyroid hormone ingestion or struma ovarii). Low uptake values may also be seen when there is increased exposure to iodine, such as with contrast dye administration or amiodarone use. If the uptake values are lower than would be expected by the clinical history, a 24-hour urine iodine may be obtained to demonstrate whether the patient has had exposure to excess iodine.[18]

The uptake of radiotracer is diffusely increased in the setting of hyperthyroidism due to Graves disease and toxic multinodular goiter. These two conditions also may be distinguished by antibody testing and US examination demonstrating the presence or absence of nodularity. Patients with clinically evident end-organ manifestations of Graves disease such as orbitopathy do not require scintigraphy to confirm the diagnosis. However, in mild cases of Graves disease lacking the characteristic clinical findings, the radionuclide study is a very useful test to rule out silent thyroiditis. In the thyrotoxic phase of silent or subacute thyroiditis, the radioiodine uptake is very low or undetectable. An experienced sonographer can distinguish these two entities, however, utilizing color Doppler interrogation (see earlier section). Furthermore, the clinical features of silent thyroiditis, including a painless thyrotoxicosis occurring within a year of childbirth in the setting of a positive family history for autoimmune thyroid disease, are sufficiently diagnostic in many cases. Similarly, nuclear scintigraphy is typically not needed to identify subacute thyroiditis, which is marked by an acutely painful gland with an elevated erythrocyte sedimentation rate.

Although most patients with Graves disease do not require scintigraphic studies, in the setting of a concomitant nodule a scintigraphic scan is beneficial to assess whether the nodule is nonfunctional and in need of possible FNA.[18] It should be noted, though, that a small, nonfunctioning nodule may be falsely reported as either warm or hot due to overlying, hyperfunctioning Graves parenchyma.

Congenital Hypothyroidism

The most common causes of congenital primary hypothyroidism are due to either a defect in thyroid gland development (dysgenesis) or a defect in thyroid hormone synthesis (dyshormonogenesis). While biochemical analysis is the mainstay of diagnostic confirmation, imaging may be necessary to identify the underlying cause or may be helpful to assess whether to treat versus observe.

Due to its ease of use, universal availability, and lack of radiation exposure, US is generally the first-line imaging technique in the evaluation of congenital hypothyroidism. In the case of thyroid dysgenesis, US most frequently identifies the location of the ectopic thyroid tissue. However, the small size of fetal thyroids means that they can be challenging to identify for an inexperienced sonographer, which may necessitate a nuclear study. Scintiscanning may also be crucial in cases of athyreosis or a lingual thyroid. For an accurate diagnosis of dyshormonogenesis, on the other hand, the combination of both US and scintigraphy may be needed. Either ^{123}I or $^{99m}TcO4^{-}$ may be used for fetal thyroid imaging, but ^{131}I should be avoided, because the radiation dose is significantly higher. Generally, ^{123}I is the preferred tracer, as it provides superior contrast resolution and allows for the concomitant administration of the perchlorate discharge test (see later section).[72]

Scintigraphic scanning for the evaluation of congenital hypothyroidism should be performed either before or shortly after the initiation of levothyroxine, because the uptake of radioiodine is dependent on TSH secretion. Normalization of serum TSH can result in misrepresentation of the underlying pathophysiology, with little or no uptake of radioactive iodine. If it cannot be performed within this narrow time window, the testing should be delayed until after the age of 3 years, when the interruption of hormone therapy no longer poses a threat to neurocognitive development.[73] To circumvent this limitation, some advocate for avoiding thyroid hormone withdrawal entirely by utilizing recombinant human TSH.[74]

Perchlorate Discharge Test

A perchlorate discharge test is used in conjunction with an ^{123}I scan to diagnose organification defects. In the setting of normal thyroid physiology, iodide is captured by thyrocytes and rapidly fixed, or organified, to thyroglobulin tyrosine residues, resulting in no free iodide within the cell. When there is a defect in organification, free iodide accumulates within the thyrocytes. Perchlorate is similarly taken into the thyrocytes but is not organified. In patients with an organification defect, administered perchlorate competes with the free iodide that is located inside of the thyrocytes and pushes it out of the cells,[72] whereas, in patients with normal organification, the perchlorate does not impact the iodide dynamics, because intrathyroidal iodine is fixed to the thyroglobulin.

A perchlorate discharge test involves administration of radioactive iodine followed by a baseline measurement of the amount of iodine captured by the thyrocytes. Oral perchlorate is then administered, and the ^{123}I activity within the thyroid is again measured after 1 hour. The ratio of the change in activity before and after perchlorate is compared with the initial activity. In an infant with normal organification, perchlorate does not change the amount of activity within the thyroid; this is termed a "negative" perchlorate discharge test. On the other hand, in children with organification defects, there is a rapid reduction in ^{123}I activity within the thyroid after the administration of perchlorate. A change in activity of greater than 10% is considered to be significant. A "positive" perchlorate discharge test therefore serves as confirmation of an organification defect.[75]

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Although CT and magnetic resonance imaging (MRI) are insensitive means of characterizing thyroid nodules, these imaging modalities do have an important role in the evaluation of patients with obstructive and substernal goiters. Cross-sectional imaging allows for determination of the presence and degree of intrathoracic extension, which is difficult, if not impossible, to assess with US. Furthermore, these modalities also aid in the assessment of the tracheal narrowing. This visualization of the effect of the goiter upon surrounding structures informs the evaluation of whether the patient's compressive symptoms are due to the thyroid or some other underlying pathophysiologic condition. Additionally, cross-sectional imaging aids in the decision to pursue surgical intervention versus observation.

Large goiters may be asymptomatic or cause varying degrees of compressive symptoms. Exertional dyspnea is present in 30% to 60%[76,77] of those with obstructive retrosternal goiters and typically occurs when the tracheal diameter is less than 8 mm.[78] Other potential compressive symptoms include cough, hoarseness, stridor, choking sensation, Horner syndrome, and dysphagia. Superior vena cava syndrome also may be seen due to compression of venous structures.

US should be performed in all patients with a goiter to assess the cervical component for findings concerning for malignancy. Once it is established that the inferior extent of the gland is not visible with US, CT or MRI is indicated. Depending on the length of the thyroid, imaging of both the neck and chest may be necessary to capture the entirety of the goiter. The decision to utilize CT versus MRI is based on provider preference. However, if CT is utilized, a noncontrasted study should be performed. If the goiter is autonomous or the patient is overtly hyperthyroid, the administration of iodinated contrast may precipitate or exacerbate preexisting thyrotoxicosis.

Cross-sectional imaging allows for the assessment of the degree of tracheal deviation and quantification of tracheal narrowing (Fig. 69.12). Pulmonary function testing with flow-volume loop study also is helpful to assess the degree of respiratory compromise, even if the patient is asymptomatic. It is also helpful for symptomatic patients to determine if other causes of dyspnea are responsible.

Cross-sectional imaging is also beneficial for preoperative evaluation of thyroid cancer for those with an invasive primary tumor or clinically apparent multiple or bulky lymph nodes.[5] In this scenario, contrasted (rather than noncontrasted) CT is recommended to improve the sensitivity of identification of nodal involvement.[5] Although there is the theoretical concern that iodinated contrast will delay the use of radioactive iodine imaging and therapy, the majority of patients can achieve sufficiently low iodine concentrations to proceed with such therapy within

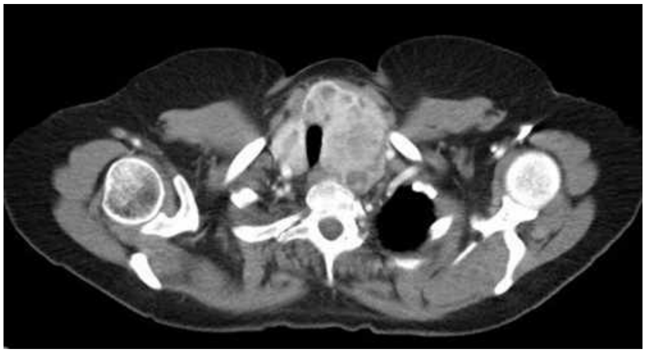

Fig. 69.12 Diagnostic image of computed tomography demonstrating tracheal deviation and narrowing due to a compressive goiter.

a month of receiving the contrast load.[79] Such a brief delay is unlikely to confer a survival disadvantage for the vast majority of thyroid cancer patients receiving radioactive iodine therapy. Alternatively, gadolinium-enhanced MRI of the neck may be used to avoid iodinated contrast entirely. The use of MRI, however, is limited by the potential for motion artifact due to swallowing and breathing.[5]

KEY POINTS

- Computed tomography or magnetic resonance imaging are important components of the evaluation of a substernal or compressive goiter to examine the degree of retrosternal extension and/or the presence of tracheal narrowing. Cross-sectional imaging is also an important component of the preoperative planning in thyroid cancer patients with bulky nodal disease.

INCIDENTALOMAS

Thyroid nodules identified on imaging studies not specifically intended for the assessment of thyroid pathology are termed thyroid incidentalomas, or incidental thyroid nodules (ITNs). It is important to recognize that the majority of these lesions represent a benign neoplasm. When these lesions do harbor a malignancy, papillary thyroid carcinoma constitutes the bulk of the cancers identified, which is generally associated with an excellent prognosis. This potentially favorable outcome is particularly important for those patients with another primary malignancy elsewhere that may have instigated the imaging study. Within this framework, diagnostic evaluation of ITNs is not always actively pursued, depending on the clinical scenario in which they are identified.

Computed Tomography and Magnetic Resonance Imaging

ITNs are one of the most common incidental findings on imaging of the neck; the prevalence is dependent on the type of imaging modality employed. Patient demographics also may have an impact on the incidence of incidentally noted thyroid nodules; women are twice as likely to have a thyroid nodule on exam compared with men,[80] and nodules are more commonly seen with increasing age.[81] Further, geographic location impacts the frequency of identification of thyroid pathology. Areas of low iodine intake are associated with higher rates of identification of thyroid nodules.[82]

Thyroid nodules are readily visualized on contrasted and noncontrasted CT; dedicated imaging of the chest is the most common source of ITNs.[83] However, the sensitivity and specificity for identifying thyroid nodules is low with CT. One study correlating the CT findings with US exams and surgical pathology found that, although CT identified the dominant nodule in half of patients, it missed mulitnodularity in 30% of patients.[84] Furthermore, CT overestimated the number of nodules in 2.2% and yielded a false-positive finding in 4.3% of patients.

While thyroid nodules are identified on screening US in up to 69% of asymptomatic individuals,[85] CT exam only uncovers thyroid abnormalities in 2% to 30% of patients.[80,86] MRI of the cervical spine identifies incidental thyroid nodules in up to 20% of scans.[87] The actual incidence of thyroid nodules on CT and MRI is unclear, however, as not all radiologists convey these findings on the final report. In retrospective studies, thyroid nodules are identified on CT in 10% to 15% of scans, but those findings are only reported in a small fraction of those exams.[87,88]

Recommendations regarding the evaluation of ITNs are sparse and nonspecific. Weighing the economic and emotional costs of pursuing a thorough diagnostic evaluation of what is most likely a benign neoplasm against the low but certainly highly concerning risk of missing a clinically significant malignancy is truly a conundrum for the radiologist. Furthermore, the exponentially rising rates of thyroid cancer diagnoses, many of which are largely attributed to increased diagnostic scrutiny,[67] have intensified the need for a well-defined management strategy regarding these common clinical entities. A white paper sponsored by the American College of Radiology recommended an algorithm for evaluation of ITNs detected on CT and MRI. In this flowchart, consideration is given to concomitant suspicious CT or MRI findings, patient life expectancy and comorbidities, patient age (<35 years or ≥35 years), and nodule size (<1–1.5 cm or ≥1–1.5 cm) when determining whether to recommend further diagnostic evaluation of ITNs with thyroid US.[89] Prospective analysis of the clinical and economic impact of such a strategy is currently lacking, however.

(^{18}F)-Fluorodeoxyglucose–Positron Emission Tomography

Incidental thyroid nodules are identified on (^{18}F)-fluorodeoxyglucose–positron emission tomography (PET) in approximately 2% to 3% of examinations (Fig. 69.13A,B).[90,91] Though studies report widely varying rates of malignancy, the finding of a focal area of increased activity in the thyroid generally is associated with a risk of malignancy of 35%.[91,92] However, the evaluation of an ITN on PET should be tempered based on the underlying malignancy that prompted the examination. In one retrospective study of ITNs assessed by PET, the median overall survival from the primary malignancy that initially prompted the imaging study was 20 months. On multivariate analysis, advanced stage of the known malignancy at the time of PET and a decision not to investigate the ITN were significant predictors of mortality.[91] Of the fraction of patients who had further investigation of the ITNs, the majority represented low-risk papillary thyroid carcinomas; 98% of the confirmed thyroid cancer cases were either stable or free of disease. The high mortality in this cohort was almost exclusively due to the poor prognosis associated with the underlying initial malignancy

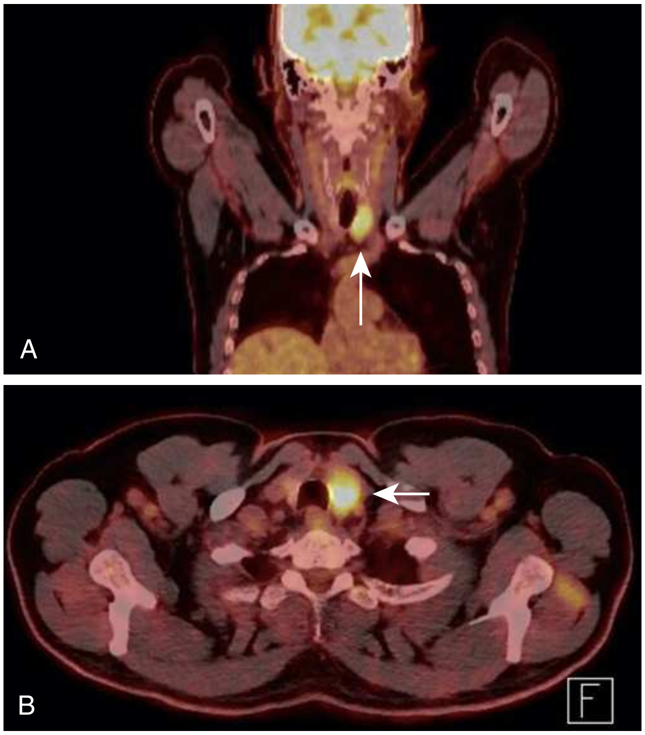

Fig. 69.13 A, Diagnostic image of an incidentally-detected (^{18}F)-fluorodeoxyglucose (FDG)-positive thyroid nodule identified on colon cancer staging scan. B, Diagnostic image of an incidentally detected FDG-avid thyroid nodule.

rather than to adverse outcomes related to the incidentally-detected thyroid cancer.[91] It is imperative, therefore, that careful consideration be given to the overall clinical context and prognosis of the underlying malignancy before undertaking further steps in the evaluation of an ITN by PET. Deliberation of whether to investigate an ITN by PET should include determination of a favorable prognosis with the underlying malignancy, consideration of patient age, and regard to comorbid conditions.

KEY POINTS

- Thyroid nodules are frequently detected incidentally on imaging of the head and neck for other reasons. These neoplasms are seldom associated with a clinically meaningful primary thyroid malignancy. Further evaluation of these incidental nodules should be performed based on the clinical context, including other primary malignancies, comorbid conditions, and patient life expectancy.

FUTURE DIRECTIONS

Although sonography and scintigraphy are well established in their role in imaging of thyroid disorders, the field continues to evolve. Continued investigation is needed to determine the appropriate applications of newer technologies such as elastography, contrasted sonography, and machine learning algorithms of sonographic risk stratification.

THYROID GLAND

The *normal thyroid gland* consists of right and left lobes that are connected by an isthmus (the so called *"butterfly gland"*). The thyroid capsule is incomplete (especially posteriorly and in the region of the isthmus), thin, and cannot be easily separated from the thyroid gland. The normal thyroid is soft and light brown to red in color with a glistening cut surface owing to colloid. The functional unit of the thyroid gland is the follicle. These are oval to spherical structures of varying sizes formed by a single layer of low-cuboidal epithelium encircling a lumen containing colloid, partly composed of thyroglobulin. The individual follicular cells show nuclei with even nuclear chromatin and inconspicuous nucleoli.[1]

The calcitonin secreting C-cells (also known as [AKA] parafollicular cells) are housed next to follicular cells within the confines of the basement membranes. The C-cells are more numerous in infants and children than in adults and are mainly seen in the central portions of the middle and upper thirds of the thyroid lobes. Interestingly, the well-publicized neural crest origin of the C-cells is now challenged by studies conducted in mouse embryos showing that C-cells arise from pharyngeal endoderm.[1,2]

The Hürthle cells, also termed "oncocytic cells," are metaplastic follicular cells with cytoplasmic eosinophilia because of enlarged mitochondria and enlarged round nuclei with prominent nucleoli. These can be seen in normal thyroid glands, but are commonly encountered in diffuse toxic goiter, longstanding goiterous nodules, chronic lymphocytic thyroiditis, and neoplasms.[1,3]

PATHOLOGIC ASSESSMENT OF THYROID LESIONS

As mentioned, the pathologic assessment of thyroid lesions includes cytopathologic examination of preoperative fine needle aspiration (FNA) specimens, intraoperative assessment/frozen section, and gross pathologic and histopathologic evaluation of surgically excised specimens.

FNA of thyroid nodules is usually performed under ultrasound (US) guidance rather than palpation. The rapid on-site evaluation (ROSE) of thyroid FNA specimens is performed by a cytopathology professional to assess the adequacy of a specimen, render preliminary diagnosis in some cases, and help with specimen triage for ancillary studies (flow cytometry, immunohistochemistry, reflex molecular studies). It has been shown that ROSE can significantly decrease the nondiagnostic rate. FNA specimens can be prepared for cytopathologic evaluation by any of the following methods: air-dried smears and alcohol-fixed smears and monolayer preparation (usually Cytolyt® solution for Thin-Prep®), cytospin, and/or cellblock prepared from the needle rinse. Thyroid FNA specimens are usually classified using a tiered reporting scheme known as the Bethesda System for Reporting Thyroid Cytology (BSRTC). Each diagnostic category of the BSRTC is associated with an assigned risk of malignancy, along with recommendations for management (Table 70.1).[4,5]

It is well known that *thyroid frozen section* diagnosis is specific but not sensitive. Most experts agree that the initial approach to diagnosing a thyroid nodule should be FNA.[6,7] With an unequivocal diagnosis of malignancy on FNA, the surgeon should proceed with the appropriate surgery for that malignant diagnosis. For thyroid nodules diagnosed as "neoplasm/suspicious for neoplasm," the limited sampling at frozen section is unlikely to be fruitful in finding a random microscopic focus of capsular or vascular invasion required for the diagnosis of follicular carcinoma.[8] However, in the current era of adjunct molecular testing of thyroid FNA specimens and conservative surgical approach to thyroid lesions, frozen section is rarely performed.

TABLE 70.1 The Bethesda System for Reporting Thyroid Cytopathology

Diagnostic Category	Risk of Malignancy (%)	Possible Management Paradigm
Nondiagnostic or unsatisfactory	5–10	Repeat FNA with ultrasound guidance
Benign	0–3	Clinical and sonographic follow-up
Atypia of undetermined significance or follicular lesion of undetermined significance	~10–30	Repeat FNA, molecular testing, or lobectomy
Follicular neoplasm or suspicious for a follicular neoplasm	25–40	Molecular testing, lobectomy
Suspicious for malignancy	50–75	Near-total thyroidectomy or lobectomy[a]
Malignant	97–99	Near-total thyroidectomy

FNA, Fine-needle aspiration.

[a] Molecular testing can be used to inform the extent of surgery.

From The 2017 Bethesda system for reporting thyroid cytopathology. *Thyroid.* 2017;27:1341–1346

KEY POINTS

- The limited sampling associated with taking frozen sections is unlikely to be fruitful in finding a random microscopic focus of capsular or vascular invasion required for the diagnosis of follicular carcinoma.

Gross pathologic examination of a thyroid is usually performed on a fresh specimen, and tumor size and appearance are documented before sections are taken. In the case of a dominant encapsulated nodule, it is recommended that the entire circumference of the nodule be sectioned, whereas for a nonencapsulated nodule one section per 0.5 cm can be submitted.[9]

KEY POINTS

- It is recommended that entire circumference of a dominant encapsulated nodule be sectioned and submitted for histopathologic examination to exclude invasive characteristics.

The *final histopathologic report* should be detailed and include all of the known prognostic parameters according to the latest synoptic reporting system. Based on the pathologic assessment and provided clinical information, the tumor stage should be documented based on the current version of the tumor-node-metastasis staging system.[9]

Pathology of Thyroid Lesions

Developmental Variations. By light microscopy the thyroglossal duct is usually lined by ciliated pseudostratified epithelium; however, the cell type may be transitional or squamous if the duct is traumatized or infected, or it may be partially or completely lost and replaced by fibrous tissue. If fluid accumulates in part of the thyroglossal duct, a thyroglossal cyst may develop. Any type of diffuse thyroid disease can involve lingual thyroid and the thyroid tissue along the thyroglossal duct tract.[10,11] Parathyroid glands, thymic tissue, small collections of cartilage, and tiny glands lined by ciliated cells may be seen in normal thyroid glands, presumably related to the development of the branchial pouches.[11]

Because of developmental variations, strips of striated muscle and adipose tissue can be encountered embedded within the thyroid parenchyma. Thyroid tissue can also be seen in perithyroidal skeletal muscle, and they should not be confused with infiltrating or metastatic carcinoma.[1]

Diffuse Enlargements of Thyroid Gland

Graves Disease/Diffuse Toxic Goiter. Grossly, the thyroid gland is diffusely enlarged up to several times the normal size.[12] The cut surfaces are fleshy and lack normal translucence because of the loss of colloid.

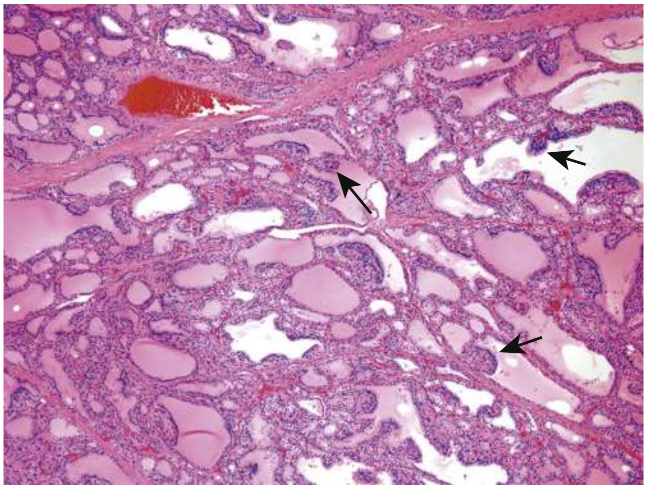

Fig. 70.1 Graves disease. Photomicrograph showing diffuse papillary hyperplasia. The individual papillae are highlighted by arrows (hematoxylin and eosin stain, 20x).

- Microscopically, there is follicular cell hypertrophy and hyperplasia. The follicular cells are tall and columnar and form papillary folds that extend into the lumina of the follicles. Infiltrates of lymphocytes are seen within the interfollicular stroma (Fig. 70.1).
- FNA biopsies are usually not performed in patients with Graves disease; only patients with one or more nodules suspicious on US are selected for FNA.[13] The FNA specimens are cellular and show features of hyperplastic goiter with lymphocytes and oncocytic cells.[14,15]

Chronic Lymphocytic Thyroiditis.

- Grossly, the thyroid gland may appear normal in size, as large goiter or atrophic, depending upon the severity and stage of involvement by chronic lymphocytic thyroiditis.[16]
- Microscopically, focal chronic lymphocytic thyroiditis is characterized by patches of lymphocytic infiltrates within thyroid parenchyma with or without associated Hürthle cell metaplasia. In more severe cases, there is diffuse lymphocytic infiltration of thyroid parenchyma with lymphoid germinal center formation, follicular cell atrophy, Hürthle cell metaplasia, and fibrosis (Fig. 70.2). In more advanced cases, little or no thyroid parenchyma is seen and is replaced by fibrosis and nodules of remaining atrophic thyroid tissue with lymphoid germinal centers.[16,17]
- FNA is usually performed in patients with chronic lymphocytic thyroiditis who present with distinct nodules or show a suspicious area on US examination (hypoechogenicity, increased vascularity,

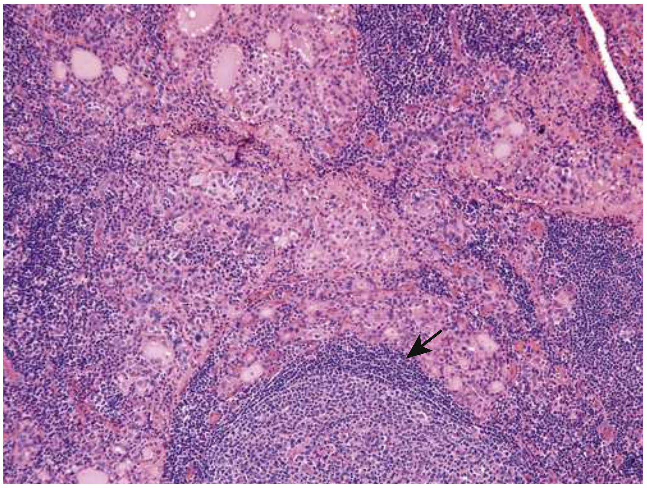

Fig. 70.2 **Chronic lymphocytic thyroiditis.** Photomicrograph showing islands of follicular cells with Hürthle cell metaplasia and brisk lymphocytic infiltrate with lymphoid germinal centers *(arrow)* (hematoxylin and eosin stain, 20×).

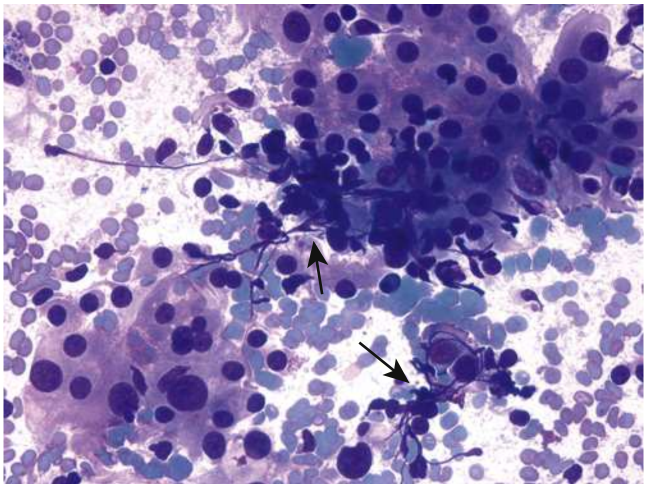

Fig. 70.3 **Chronic lymphocytic thyroiditis.** Photomicrograph of fine-needle aspiration specimen showing Hürthle cells infiltrated by lymphocytes *(arrows)* (air-dried smear preparation, Diff-Quik® stain, 40×).

microcalcifications). The cytologic preparations show follicular cells and Hürthle cells in a background of lymphocytes with little or no colloid. The lymphocytes are usually seen in the background and infiltrating the follicular and/or Hürthle cell groups (Fig. 70.3).[18]

- The other forms of thyroiditis encountered in thyroid surgical specimens include Riedel thyroiditis (AKA Riedel struma), combined Riedel's struma[19] and fibrosing chronic lymphocytic thyroiditis,[20] nonspecific-focal chronic lymphocytic thyroiditis, granulomatous/subacute thyroiditis,[21] palpation thyroiditis,[22] and, rarely, specific infectious thyroiditis.[23]

Nodular Enlargements and Nodules

Nontoxic Nodular Goiter.

- The pathologic stages of the nontoxic nodular goiter include one or more of the following microscopic features:[24,25]
    - Hyperplastic stage: This represents response of the thyroid follicular cells to thyroid-stimulating hormone or other growth and/or stimulants. The follicular cells are tall and columnar in shape, with enlarged and hyperchromatic nuclei. The epithelial hyperplasia may also lead to papillary architecture.
    - Colloid accumulation stage (AKA colloid goiter): The thyroid follicles may undergo involution, and the epithelium become low-cuboidal and flattened. Some follicles grow larger than normal and contain excessive colloid. On gross examination the gland has a characteristic glistening cut surface because of excess colloid accumulation.
    - Nodular stage: The persistence of hyperplasia along with involution of some thyroid follicles gives rise to a heterogeneous appearance of the thyroid gland. The vascular network is altered because of overgrowth, leading to degenerative changes with ensuing fibrosis. This combination leads to poorly demarcated yet well-circumscribed nodules known as hyperplastic/adenomatoid nodules.
- The FNA specimen from a hyperplastic/adenomatoid nodule in multinodular goiter shows the following cytomorphologic features:[26]
    - Abundant thin and watery colloid, small round- to oval-shaped follicular cells with dark nuclei arranged in monolayer sheets, follicular groups, or single cells (Fig. 70.4).
    - The cytoplasm is usually scant in follicular cells and can show numerous, small, blue-black granules.

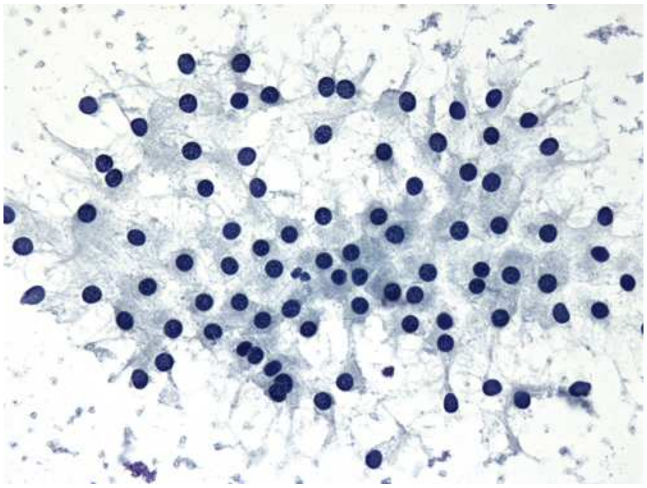

Fig. 70.4 **Nodular goiter.** Photomicrograph of fine-needle aspiration specimen showing loosely cohesive group of follicular cells with small round nuclei (alcohol-fixed smear preparation, Papanicolaou stain, 40×).

    - Macrophages are usually present, and their number correlates with presence or absence of degenerative changes or a cystic component
    - The FNA specimens from a hyperplastic/adenomatoid nodule usually are cellular and contain an admixture of follicular cells and oncocytic (Hürthle) cells arranged in monolayer sheets or three-dimensional groups in a background of thin watery colloid and macrophages.

Thyroid Neoplasms. All neoplasms that arise from thyroid epithelium can have some functional capacities. They may respond to TSH and even produce excessive amounts of thyroid hormones or, if medullary carcinoma, may release abnormal quantities of calcitonin or other peptide hormones.[1,27] Immunohistochemical localization of thyroid transcription factor-1 (TTF-1), thyroglobulin, paired box 8 (PAX8), or calcitonin aids in the classification of unusual thyroidal tumors and in providing definite identification of metastatic thyroid carcinomas.[1,27]

Benign Neoplasms

Adenomas and Adenomatous Nodules.

- Classically, the follicular adenoma is described as a solitary, encapsulated lesion having a uniform internal architecture that is different

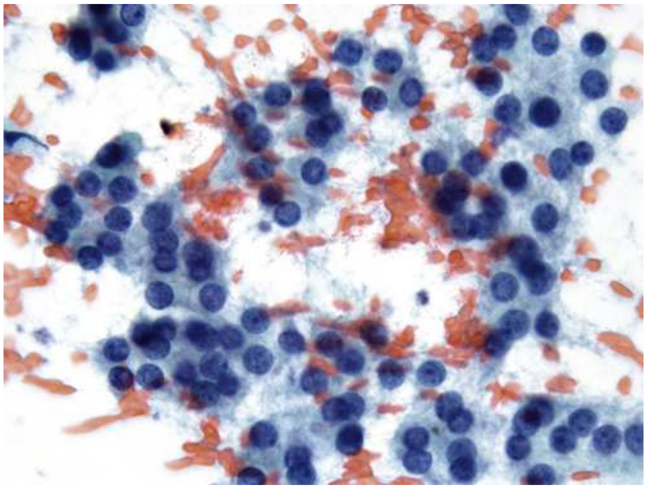

Fig. 70.5 Follicular neoplasm/suspicious for follicular neoplasm. Photomicrograph of fine-needle aspiration specimen showing a monotonous population of follicular cells arranged in microfollicles. Notice the round nuclei with even chromatin pattern (alcohol-fixed smear preparation, Papanicolaou stain, 40×).

from the surrounding thyroid based on growth pattern and cellular features.[1] However, it is often difficult based on morphologic features to clearly separate hyperplastic/adenomatous nodules arising in the background of goiter or thyroiditis from adenomas.

- By molecular analysis, up to 70% of the hyperplastic/adenomatoid nodules in goiter are clonal, thus representing neoplastic proliferations.[28] Therefore, it would not be farfetched to expand the pathologic definition of follicular adenoma to a follicular-derived partially or completely encapsulated or circumscribed nodule with a distinct growth pattern that is different from the surrounding thyroid parenchyma and lacks invasive features. These can be multiple and arise in a background of normal thyroid or in the setting of nodular goiter, toxic goiter, and thyroiditis.[1]
- By gross pathologic examination, follicular adenomas and adenomatous nodules are well-circumscribed and are often demarcated from the adjacent tissue. Their size varies from about 1 mm to several centimeters in diameter. A classic adenoma is fleshy and pale; hemorrhage, fibrosis, and cystic change may be evident. Calcifications may be seen in longstanding lesions.[1,27]
- By light microscopy, an adenoma or an adenomatous nodule is encapsulated, shows follicular, solid or rarely papillary growth patterns, and lacks capsular and/or lymphovascular invasion. The lesional cells can be cuboidal or columnar in shape with small, round nuclei with an even chromatin pattern.[27]
- In some cases, the adenoma can be hyperfunctioning (AKA toxic adenoma). In adolescents, especially females, many hot, or toxic, nodules contain numerous papillae, often sufficient in number to cause a pathologist to suggest a diagnosis of papillary carcinoma.[29]
- By immunohistochemistry, all adenomatous nodules and adenomas express TTF-1 and thyroglobulin and show cytokeratin expression similar to normal thyroid parenchyma.[30]
- FNA specimens obtained from follicular adenoma are cellular and show a monotonous population of follicular cells arranged in cohesive groups with nuclear overlapping and crowding and/or microfollicles. The individual cells are enlarged (compared with background red blood cells) and contain round nuclei with an even chromatin pattern (Fig. 70.5).
- Post-FNA, changes can be seen on gross examination as focal hemorrhage and on microscopic examination in the form of hemorrhage, fibrosis, endothelial proliferation, pseudovascular and capsular invasion, and even partial or total infarction.[31-33] These changes are often prominent in cases of Hürthle cell adenoma or adenomatous nodule.
- Several morphologic variants of follicular adenoma have been described. These include:
  - *Atypical follicular adenoma*: This term is reserved for cases that exhibit some atypical features, including foci of necrosis, excess cellularity, mitoses, and lack of capsular and/or vascular invasion. The recent World Health Organization (WHO) classification includes the term "follicular tumor of uncertain malignant potential" for the encapsulated follicular pattern lesions with irregular tumor capsule interface, incomplete capsular involvement, and mitotic foci. The great majority of such cases behave as benign adenomas.[27]
  - *Hyalinizing trabecular neoplasm of the thyroid* (HTN), AKA *hyalinizing trabecular adenoma*: This is a morphologically distinct follicular0derived lesion. Microscopically, the lesional cells grow in nests that are surrounded by dense hyaline stroma. The nuclear features of the follicular cells are similar to those seen in papillary carcinoma. However, a benign behavior has so far been described in all cases of hyalinizing trabecular adenoma that show classical histology. By immunohistochemistry, the cells of hyalinizing trabecular adenoma stain positive for thyroglobulin and cytokeratin-19 and negative for calcitonin. *RET/PTC* rearrangements have been detected in HTN; however, recent studies show that *PAX8-GLIS3* and *PAX8-GLIS1* fusions are specific alterations of HTN.[34,35]
  - The other morphologic variants of follicular adenoma include, signet ring cell follicular adenoma, spindle cell follicular adenoma, and lipoadenoma adenomlipoma.[35]

Malignant Neoplasms

The most common malignant neoplasms that originate in the thyroid are well-differentiated carcinomas of follicular cell origin; most are papillary carcinomas (Table 70.2).[1,27]

Papillary Thyroid Carcinoma

Papillary thyroid carcinoma (PTC) comprises approximately 80% of thyroid carcinomas affecting adults and children in countries with sufficient dietary iodine intake. PTC occurs frequently in women and is rarely familial.[1,13,36]

- Grossly, papillary cancers can present in various sizes, and are predominantly solid, although small cystic foci may be present. Cystic cancers can occur, with one or more cystic spaces occupying most of the neoplasm.[1]
- Small papillary carcinomas (*microcarcinomas*) are defined as being 1 cm or less in diameter. The prevalence of these lesions ranges from 6% to 36% (depending upon the studied population and how thoroughly the thyroid gland was examined). When visible on gross examination, they present as small, irregular, firm scars, as soft foci of discoloration, or as tiny calcified lesions.[1,27]
- Readily identifiable calcifications or specks of calcified material and crystals may be present in the cyst fluid. The cut surface of tumor may appear granular because of exuberant papillary formations.[27]
- Fibrosis is common in and around papillary carcinomas, and it may be distributed in an extremely irregular fashion, grossly and microscopically.
- Most PTCs are infiltrative within the thyroid gland; however, about 10% to 20% are grossly encapsulated. Encapsulation of the primary carcinoma is associated with a lower frequency of lymph node involvement.[1,37,38]

TABLE 70.2 World Health Organization Pathologic Classification of Thyroid Neoplasm of Follicular Cell Origin

Neoplasms

Other Encapsulated Follicular-Patterned Thyroid Tumors

1. Noninvasive follicular thyroid neoplasm with papillary-like nuclear features
2. Follicular tumor of uncertain malignant potential
3. Well-differentiated tumor of uncertain malignant potential

Papillary Thyroid Carcinoma

1. Conventional type
2. Follicular
3. Encapsulated
4. Microcarcinoma
5. Tall cell
6. Columnar cell
7. Oncocytic
8. Hobnail
9. Diffuse sclerosing
10. Cribriform morular
11. Solid/trabecular
12. Warthin-like
13. Others

Follicular Thyroid Carcinoma

1. Minimally invasive
2. Encapsulated angioinvasive
3. Widely invasive

Hürthle Cell Carcinoma

1. Minimally invasive
2. Encapsulated angioinvasive
3. Widely invasive

Poorly Differentiated Carcinoma

Anaplastic/Undifferentiated Thyroid Carcinoma

From *WHO Classification of Tumours of Endocrine Organs.* 4th ed. Vol 10. Lyon: WHO/IARC Press; 2017.

- By light microscopy, PTC contain papillae. The papillae contain well-developed fibrovascular cores and are covered with a single layer of the epithelial cells; the amount of true papillae can be variable within a PTC (Fig. 70.6).[1,27]
- PTC may show a solid growth pattern, may be composed of follicles (follicular variant), or may be almost entirely papillary.[1,27]
- The microscopic diagnosis of PTC is based on characteristic nuclear cytology of lesional cells. These are usually cuboidal to low columnar and contains nuclei that are relatively large and irregular in shape, with pale, empty, or "ground glass" chromatin, folds/grooves, indentations, and cytoplasmic inclusions. The nucleolus is often inconspicuous and eccentric in location (lies near the nuclear membrane) (Fig. 70.6).[39,40 27,41]
- About one-third to one-half of papillary carcinomas form laminated calcific spherules known as psammoma bodies. Anytime a psammoma body is found in normal thyroid tissue, cervical lymph nodes, or perithyroidal soft tissue, PTC should be excluded by careful screening of histologic sections.[42,43] Structures resembling psammoma bodies are occasionally found within the colloid of follicles in adenomas or adenomatous nodules, especially those composed of oxyphilic cells, where they seem to arise from calcification of inspissated colloid; these structures should not be equated with psammoma bodies.[44,45]

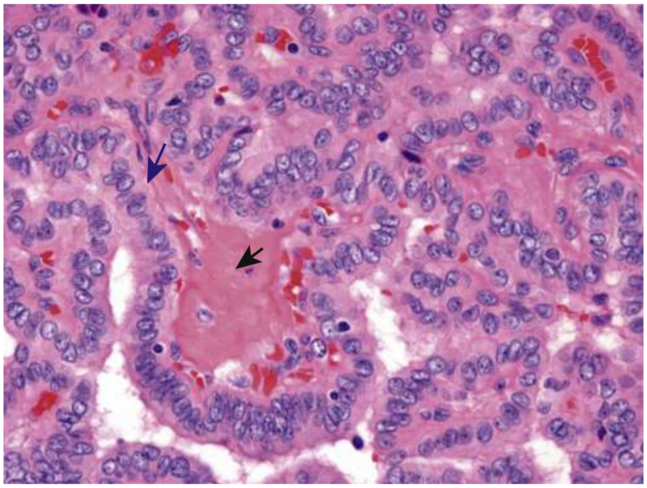

Fig. 70.6 **Papillary thyroid carcinoma, classic variant.** Photomicrograph showing complex papillae with fibrovascular core *(black arrow)* and tumor cells lining the papillae with nuclear features of papillary thyroid carcinoma *(blue arrow)* (hematoxylin and eosin stain, 40×).

- Lymphocytic infiltration is often present within and around papillary carcinomas.
- Multiple intrathyroidal foci of tumor and metastasis to cervical lymph nodes are common and likely attributed to lymphatic invasion by tumor.[46]
- If a nodal metastasis is cystic, it must be differentiated from other cystic benign lesions such as branchial cleft cyst.[47]
- Blood vessel invasion (angioinvasion) by papillary carcinoma is rare, and metastatic foci in distant sites are unusual (~5%–7% of cases), with the lungs most frequently involved.[48]
- The diagnosis of PTC in FNA specimens is based on characteristic nuclear morphology, regardless of cytoplasmic and architectural features.[26,49]
  - The specimens are usually cellular, and the tumor cells are arranged as papillary groups (Fig. 70.7A and B), three-dimensional tissue fragments, or single cells in the background of thin or thick colloid (AKA "ropy" or "chewing gum" colloid). Some cases can show calcifications, psammoma bodies, or variable numbers of macrophages as a result of cystic changes.
  - The individual tumor cells are enlarged and oval in shape, with nuclei showing chromatin clearing, membrane thickening, intranuclear grooves, and pseudoinclusions (Fig. 70.8A and B).
  - Some cases may also demonstrate multinucleated giant cells.

KEY POINTS

- The diagnosis of papillary thyroid carcinoma in fine-needle aspiration specimens is based on characteristic nuclear morphology, regardless of cytoplasmic and architectural features.

Variants of Papillary Cancer

Follicular variant of papillary thyroid carcinoma (FVPTC) is the most common histologic variant of papillary carcinoma after the usual or classic variant; it is characterized by formation of follicles lined by cells with nuclear features of papillary carcinoma. FVPTC clinically behaves similar to the conventional papillary carcinoma.[50] Although FVPTC is a variant of papillary carcinoma (based on cytology and clinical

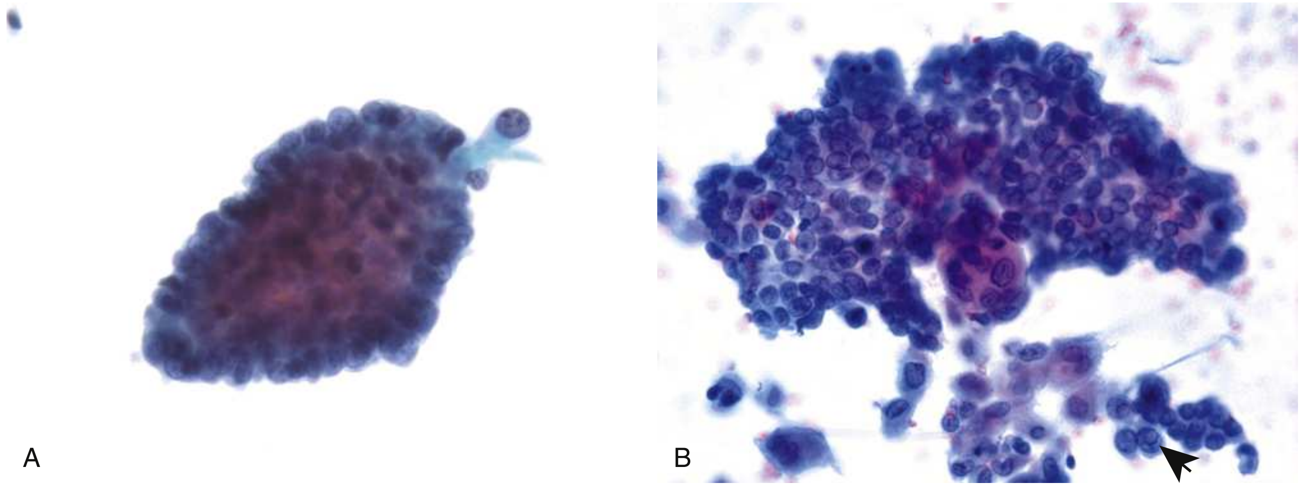

Fig. 70.7 Papillary carcinoma. Photomicrographs of fine-needle aspiration specimen showing papillary formation containing tumor cells. Note the intranuclear inclusion in B *(arrow)* (alcohol-fixed smear preparations, Papanicolaou stain, 40×).

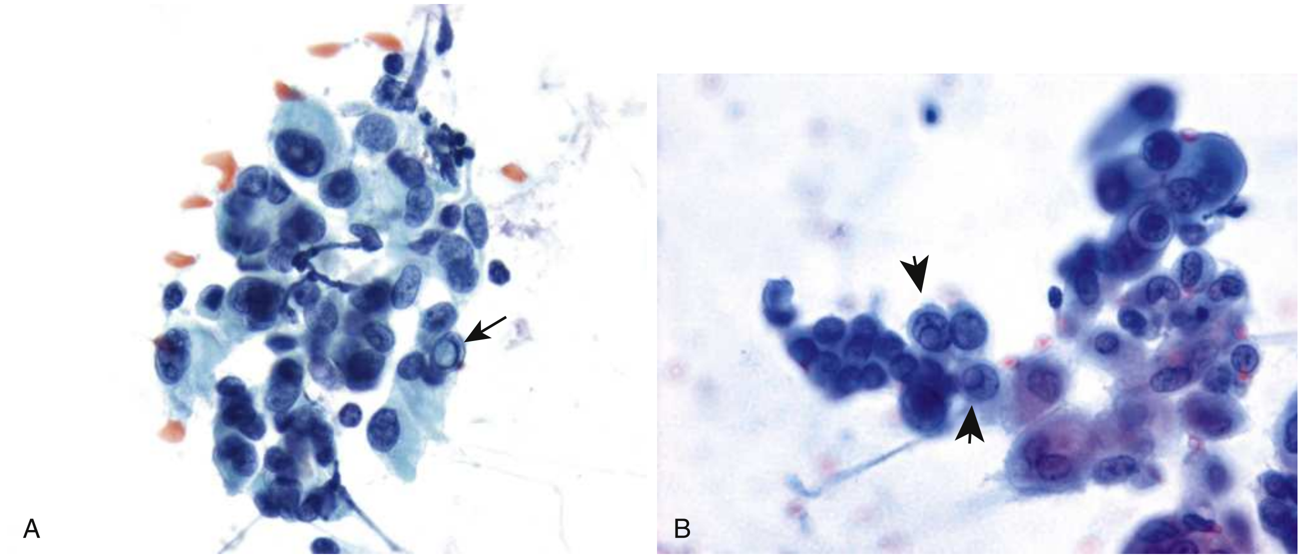

Fig. 70.8 Papillary thyroid carcinoma. Photomicrographs of fine needle aspiration specimen showing prominent intranuclear inclusions *(arrow)* (alcohol fixed smear preparations, Papanicolaou stain, 60×).

behavior), it does share some morphologic and clinical features with follicular carcinoma. These include a follicular growth pattern, encapsulation, capsular and vascular invasion, and distant metastases to lung and bone. Gene expression profiling studies have shown that some cases of FVPTC will have a similar profile to follicular carcinoma.[51,52]

FVPTC can present as the following:

- The *encapsulated variant* refers to the follicular variant, which is characterized by the presence of a capsule around the lesion. These lesions are associated with an excellent prognosis.[1] Some of these cases are readily identifiable as carcinoma because of presence of invasion into the tumor capsule and/or vascular invasion. However, cases without invasive characteristics and with the subtle presence of nuclear features of PTC can be mistaken for adenomatoid nodule or follicular adenoma.[40] In 2015, a multidisciplinary panel evaluated a large cohort of patients with FVPTC with clinical follow-up ranging from 10 to 26 years confirmed that noninvasive encapsulated FVPTC is free of recurrences and any metastatic involvement.[53] The panel suggested removing the word "carcinoma" for noninvasive encapsulated FVPTC and renaming it "noninvasive follicular thyroid neoplasm with papillary-like nuclear features" (NIFTP). This entity was defined by a set of histopathologic features including a noninvasive follicular patterned neoplasm with nuclear cytology of PTC, lack of any necrosis, and papillary architecture (Fig. 70.9).[53,54]
- Unencapsulated and infiltrative tumor.
- The diffuse follicular variant, which diffusely involves the thyroid, leads to total replacement of thyroid by tumor. Both lymph node and distant metastases (pulmonary) are common in this variant.[50,55]
- The macrofollicular variant of FVPTC is composed almost entirely of distended, colloid-filled follicles of moderately uniform size and shape, and the characteristic nuclei of PTC confirm the diagnosis.[56,57]

KEY POINTS

- Noninvasive follicular thyroid neoplasm with papillary-like nuclear features, formerly classified as noninvasive follicular variant of papillary thyroid carcinoma, is defined by a set of histopathologic features including a noninvasive follicular patterned neoplasm with nuclear cytology of papillary thyroid carcinoma, lack of any necrosis, and papillary architecture.

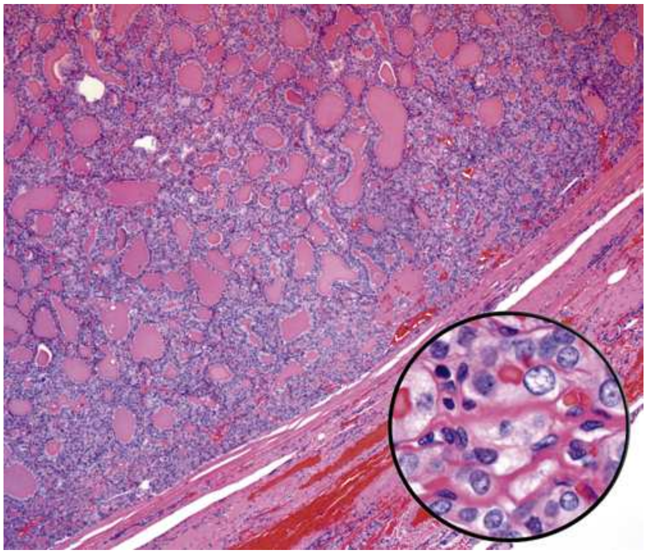

Fig. 70.9 **Noninvasive follicular thyroid neoplasm with papillary like nuclear features.** Photomicrograph showing a encapsulated follicular patterned neoplasm with nuclear features of papillary thyroid carcinoma *(inset)* (hematoxylin and eosin stain, 10×; inset 40×).

FNA specimens from FVPTC show enlarged follicular cells arranged in monolayer sheets, as well as follicles of varying sizes and shapes in a background of thin watery colloid. Usually, the diagnostic nuclear features are scarce, because of which some specimen will diagnosed as either follicular neoplasm/suspicious for follicular neoplasm (Bethesda IV) or suspicious for PTC (Bethesda V).[26]

The *tall cell variant* is considered as an aggressive variant of PTC. It is commonly occurs at older age, and a mortality rate of 25% has been reported.[58]

- The tumor cells are elongated (three times as long as they are wide) and contain eosinophilic cytoplasm.
- The tall cell variant often shows extrathyroidal soft tissue extension and vascular invasion (20%–25%).[59,60]
- The FNA specimen tall cell variant of PTC shows oncocytic tumor cells with readily identifiable nuclear features of PTC. The intranuclear inclusions can small and multiple, giving rise to so-called “soap bubble” appearance.[61,62]

The other less common variants of PTC include:

- *Diffuse sclerosis variant* (DSV), which diffusely permeates lymphatic channels within one lobe or of the entire thyroid and is accompanied by severe lymphocytic thyroiditis with interstitial fibrosis. Psammoma bodies are numerous in DSV. It occurs more often in young people, is virtually always accompanied by lymph node metastases, and often has pulmonary metastases.[63]
- *Solid variant*, which shows mainly or exclusively a solid growth pattern. It is usually seen in young people.[64]
- *Columnar cell variant* is a rare tumor composed of clear cells with marked nuclear stratification.[65]
- *Warthin-like papillary carcinoma* morphologically resembles a benign parotid lesion. This variant appears to have the same spectrum of behavior as classic PTC.[66]
- *Hobnail variant,* a rare and clinically aggressive variant of PTC that is characterized by a micropapillary growth pattern, similar to that encountered in tumors found at other biopsy sites (ovary, peritoneum, breast, bladder, kidney, and lung).[67-69]
- *Cribriform-morular variant.*[35,70]
- PTC with *Ewing family tumor elements.*[35,71]
- PTC with *ETV6-NTRK3 translocation.*[35,72]

Rarely PTC can show morphologic features indicative of aggressive clinical behavior. These include easily found mitotic figures, enlarged or hyperchromatic nuclei, abnormal DNA content, necrosis, and regions of nondescript neoplastic cells often growing in sheets (loss of differentiation).[50,73]

Follicular Carcinoma

Follicular carcinoma accounts for approximately 5% or less of all thyroid carcinomas in the United States. It is nearly always encapsulated and grossly resembles follicular adenoma.[1,27]

- It presents as a solid, encapsulated nodule with a well-developed capsule of variable thickness. In some cases tumor invasion beyond the capsule, and even venous invasion, can be seen grossly.
- On microscopic examination, follicular carcinomas most often have a microfollicular pattern and resemble a cellular follicular adenoma. Mitotic figures can be seen.
- As per WHO. follicular carcinomas can be classified as (1) localized, *minimally invasive* and (2) *widely invasive* cancers.[27]
- *Minimally invasive follicular carcinoma* is recognized by its penetration into and through the capsule that surrounds it and by its limited invasion into vessels at its periphery (less than four vessels). A minimally invasive carcinoma can present as a metastatic lesion. Multiple sections of the periphery of the neoplasm may be necessary to find the invasion.[74]
- *Widely invasive follicular carcinoma* extensively infiltrates the thyroid parenchyma and vascular channels (four or more vessels) within the gland or even in the perithyroidal tissues.[27]
- Follicular carcinoma has little tendency to invade lymphatic vessels and to spread to lymph nodes. Hematogenous spread to the skeleton, lungs, brain, liver, and other tissues occurs.
- Capsular “invasion” and “penetration” may be mimicked by post-FNA effect.
- FNA cannot distinguish between a follicular adenoma and carcinoma based on cytomorphologic features. The specimens are usually cellular and show a monotonous population of enlarged follicular cells arranged in three-dimensional groups with nuclear overlapping and crowding and microfollicles. Similar features can also be encountered in aspirates representing cellular adenomatoid nodules.[75]

KEY POINTS

- The minimally invasive follicular carcinoma is recognized by its penetration into and through the capsule that surrounds it and by its limited invasion into vessels at its periphery (less than four vessels).

Hürthle Cell (Oncocytic Follicular) Tumors

Hürthle cell tumors can be divided into benign and malignant categories by careful adherence to strict pathologic criteria defined for follicular carcinoma. More importantly, these pathologic distinctions predict clinical behavior.[3,27,76]

- Most oncocytic (Hürthle cell) neoplasms behave as follicular carcinomas; that is, pathologically the capsule or vessels should be assessed for invasion.[3]
- Oncocytic follicular (Hürthle cell) carcinomas should be considered a separate category of thyroid neoplasms from true follicular cancers. They can metastasize to regional lymph nodes as well as spread hematogenously; in addition, histologic evidence of invasive characteristics is found more commonly in oncocytic cancers than in nononcocytic follicular tumors.[50,77]

- FNA specimens of Hürthle cell neoplasms contain numerous Hürthle cells arranged in sheets and as single cells. The cells may demonstrate random nuclear pleomorphism; however, this feature is not helpful in differentiating between adenoma and carcinoma. The background shows mostly thick colloid, which on occasion maintains the round shape of the follicular lumen.[3]

KEY POINTS

- Hürthle cell (oncocytic follicular) carcinomas should be considered a separate category of thyroid neoplasms from true follicular cancers. They can metastasize to regional lymph nodes and spread hematogenously.

High-Grade Thyroid Carcinoma

The pathologic term "high-grade thyroid carcinoma" has been proposed (not endorsed by the current WHO classification of thyroid tumors) by expert thyroid pathologists to include malignant tumors of thyroid that show recognizable architectural and cytologic patterns of differentiated thyroid cancer, usually papillary, with high-grade pathologic features. These tumors often are large and show nuclear pleomorphism, foci of tumor necrosis and numerous mitotic figures, multifocal vascular invasion, and grossly identifiable extrathyroidal extension and are associated with regional and distant metastases.[50,78] It is important not to confuse these with poorly differentiated thyroid carcinomas (PDTCAs).

Poorly Differentiated Carcinoma

PDTCAs are a heterogeneous group of tumors.[27] They generally lack the usual histologic features and exceptional aggressiveness of anaplastic carcinomas.[79,80]

- The pathological features of PDTCA are solid/trabecular/insular growth, large size, frequent extrathyroidal extension, extensive vascular invasion, presence of necrosis, and increased mitotic activity (Fig. 70.10).[81]
- They may show elements of well-differentiated carcinoma, and less frequently anaplastic carcinoma.[82,83]
- Cytologic preparations representing PDTCA can be cellular, containing monotonous population of cells with nuclear overlapping and crowding with mitoses and single-cell necrosis (apoptosis). Some of these cases may resemble a secondary tumor of thyroid with neuroendocrine differentiation. Therefore, a thyroid origin should be confirmed by immunohistochemistry.[84,85]

Anaplastic Carcinoma

Fewer than 5% of thyroid carcinomas may be classified as anaplastic or undifferentiated. These usually occur in elderly people, more often women.[81,86]

- Most anaplastic carcinomas (50%–70%) will show remnants of well-differentiated follicular or papillary carcinoma or sometimes an adenoma or adenomatoid nodules, confirming the clinical impression that anaplastic carcinomas arise out of low-grade tumors.[81,87]
- Light microscopic examination shows varied histologic patterns, easily found mitotic figures, and regions of tumor necrosis.[88]
- The tumor cells show marked nuclear pleomorphism and can show squamous cell differentiation, sarcomatous appearance, bizarre giant cells, and, less commonly, giant cells resembling osteoclasts (Fig. 70.11).[88]

FNA specimens from anaplastic carcinoma can be readily classified as malignant because of readily identifiable features of poorly differentiated malignant neoplasm.[88]

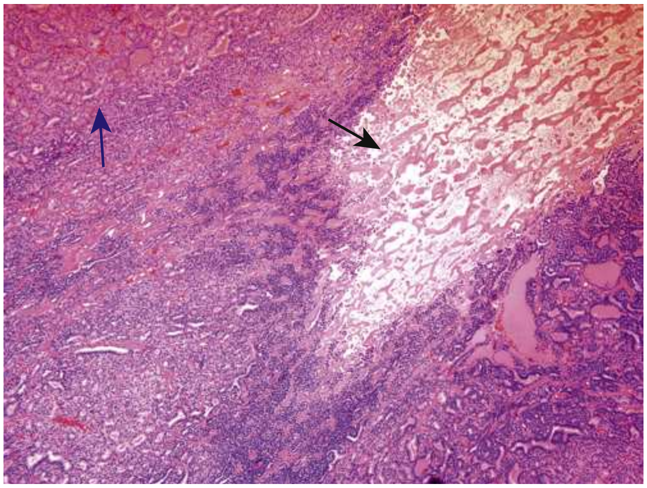

Fig. 70.10 Poorly differentiated carcinoma. Photomicrograph showing poorly differentiated carcinoma with solid growth pattern and foci of confluent tumor necrosis *(black arrow)*. Note the presence of elements of well-differentiated thyroid carcinoma *(blue arrow)* (hematoxylin and eosin stain, 20×).

Familial Follicular-Derived Thyroid Tumors

PTC and other follicular-derived thyroid tumors can be seen in other familial syndromes; these include familial adenomatous polyposis syndrome, PTEN hamartoma syndrome, McCune–Albright syndrome, Carney complex, and Peutz–Jeghers syndrome. Strong associations between *DICER1* mutations and differentiated thyroid carcinoma have also been reported.[72,81,89]

Medullary Carcinoma

Medullary carcinoma constitutes approximately 5% of thyroid carcinomas, originates from C-cells, may be sporadic or familial, and may be associated with disorders of other endocrine glands.[27,90]

- Medullary carcinomas on gross examination present as firm, white or yellow circumscribed nodules, some with infiltrative margins.[27]
- On light microscopic examination, the cells are rounded or polygonal or may be spindled. They are arranged as a diffuse solid mass, as islands separated by fibrous tissue (usually dense or hyalinized), as trabeculae or ribbons of cells, and (uncommonly) as glandular structures.[27]
- The tumor cell nuclei are rounded or elongated; occasional nuclei are large and irregular with "stippled" chromatin, also known as a salt and pepper pattern.[27] Amyloid is frequently present, both in the primary neoplasms and in the metastatic foci (~75% of cases).
- Both tumor stroma and the amyloid may undergo calcification (Fig. 70.12).[27]
- Medullary carcinomas nearly always produce calcitonin, although a few may lack this peptide.
- The tumor can invade both lymphatic and blood vessels; cervical nodes metastases are common.[91,92]
- The familial medullary carcinomas are usually bilateral and multicentric. Other family members may have C-cell hyperplasia and medullary carcinomas of microscopic size, some of which may have already spread to lymph nodes. In this situation, the so-called C-cell hyperplasia is premalignant.[1,27,93]
- A few neoplasms have been reported as mixed medullary and follicular carcinoma, which appears to represent joint C-cell and follicular cell proliferations, but these are rare.[1,27]
- FNA specimens of medullary carcinoma can show different morphologic patterns. A majority show round to oval tumor cells

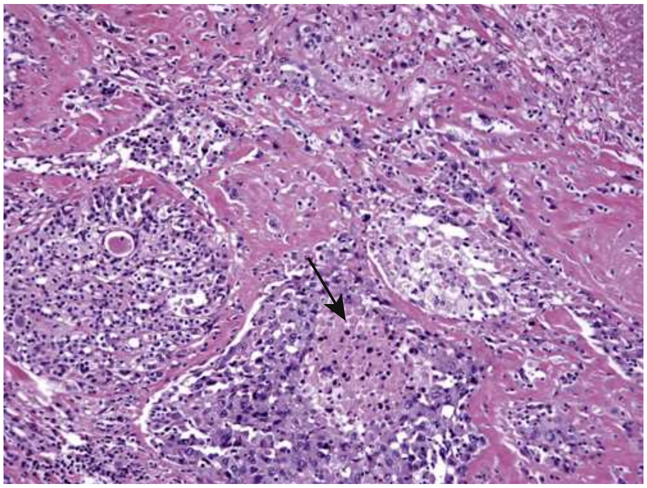

Fig. 70.11 Anaplastic carcinoma. Photomicrograph showing an undifferentiated malignant neoplasm with foci of tumor necrosis *(arrow)* (hematoxylin and eosin stain, 20×).

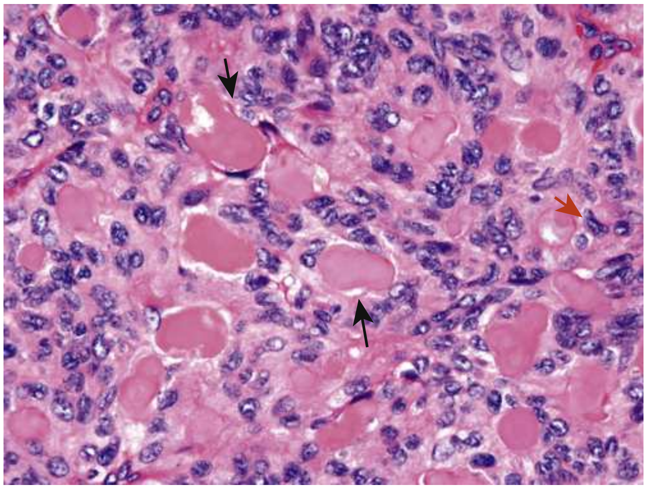

Fig. 70.12 Medullary carcinoma. Photomicrograph showing epithelioid and spindle-shaped tumor cells with stippled chromatin pattern *(red arrow)* and amyloid appearing an acellular eosinophilic deposits *(black arrows)* (hematoxylin and eosin stain, 20×).

arranged as single cells and loosely cohesive tissue fragments. The nuclear chromatin of the individual tumor cells is similar to that seen in neuroendocrine tumors, that is, stippled chromatin. Tumor cells of medullary carcinoma can either spindle-shaped or plasmacytoid in appearance (nucleus located at the edge of cell as seen in plasma cells) or contain oncocytic cytoplasm. Amyloid can be seen in the background or closely associated with tumor cells.[26,94] The diagnosis of medullary thyroid carcinoma is confirmed by performing immunostaining for either calcitonin and thyroglobulin.[26] An aliquot of the FNA specimen can also be submitted for calcitonin level determination.[95]

TUMORS WITH THYMIC OR RELATED BRANCHIAL POUCH DIFFERENTIATION

This category of primary thyroid tumors includes lesions that by morphology, immunohistochemistry, and electron microscopy show thymic or related branchial pouch differentiation. The list includes *intrathyroidal thymoma, spindle epithelial tumor with thymus-like differentiation,* and *carcinoma showing thymus-like differentiation.*[35]

RARE TUMORS OF THYROID GLAND

This list includes the following.

- *Mucoepidermoid carcinoma*, which microscopically resembles mucoepidermoid carcinoma of the salivary glands.[96]
- *Sclerosing mucoepidermoid carcinoma with eosinophilia.* This tumor usually originates in a thyroid gland with chronic lymphocytic thyroiditis and shows both squamous and glandular differentiation in a background of fibrotic stroma and inflammatory infiltrate rich in eosinophils.[97]
- *Mesenchymal tumors.* These tumors arise from the nonepithelial components of the thyroid gland and include leiomyoma, solitary fibrous tumor, angiosarcoma, and leiomyosarcoma.[35]
- *Lymphoma.* Primary lymphoma of the thyroid gland is rare, and most arise in the background of chronic lymphocytic thyroiditis. Most primary thyroid lymphomas are diffuse and are of B-cell type. Secondary involvement of thyroid gland by lymphoma can occur in 20% of patients with generalized lymphoma.[98,99]

Malignant Tumors Arising in Ectopic Thyroid Tissue

These include tumors arising in the thyroglossal duct tract, sublingual and lingual ectopic thyroid tissue, and struma ovarii. Papillary carcinoma of the classic type is the most common tumor arising in the thyroglossal duct tract. Because of this, carcinoma arising in this location can be easily diagnosed on FNA.[11,100,101]

Secondary Tumors

The most common tumors that metastasize to the thyroid are carcinomas of the breast, lung, colon, and kidney. These can also clinically mimic a primary thyroid neoplasm. The pathology diagnosis (FNA and histopathology) is based upon morphologic similarities between the primary and metastatic tumor and confirmation by appropriate immunohistochemical stain, such as thyroglobulin. In rare instances the secondary tumors can involve a preexisting primary thyroid neoplasm.[102,103]

SUMMARY AND FUTURE DIRECTIONS

This chapter has reviewed and illustrated the key histopathologic and cytological features of nonneoplastic and neoplastic lesions of the thyroid gland. Advances in cytologic diagnosis and classification of specific morphologic features has allowed FNA cytology of thyroid nodules to become part of the clinical approach to the treatment and follow-up of such nodules. Discussion has also included newly described entities such as NIFTP and its separation from the invasive follicular variant of papillary carcinoma, which continues to evolve with long term follow-up studies showing its extremely low risk prognosis.

Thyrotoxicosis is a biochemically defined state caused by an excess of circulating thyroid hormones: the term hyperthyroidism should only be used when the cause of thyrotoxicosis is excessive production of thyroid hormone by the thyroid gland. Graves disease (GD), accounts for 60% to 80% of cases of hyperthyroidism. Excessive levothyroxine dosage and destructive thyroiditis are the most common examples of thyrotoxicosis without hyperthyroidism.

GD is characterized by hyperthyroidism, a diffusely enlarged thyroid gland, and, in around one-quarter of patients, orbitopathy (GO). Pretibial myxedema (thyroid dermopathy) and thyroid acropachy are much less common extrathyroidal manifestations. Where present, these extrathyroidal features make the diagnosis possible clinically, but in many patients presenting only with biochemical evidence of thyrotoxicosis the diagnosis requires confirmation by further laboratory testing before a suitable therapeutic strategy can be chosen.

GD is caused by autoantibodies that mimic the action of thyroid-stimulating hormone (TSH) by binding to and activating the TSH receptor (TSH-R). As with most autoimmune disorders, a combination of many different genetic and environmental factors may contribute to the etiology. Family clustering and associated nonthyroidal autoimmune diseases are often found in GD patients. The cause of the extrathyroidal features is not yet entirely clear, which has hampered the development of optimal treatment for these complications, but recent developments have suggested new approaches.

HISTORICAL BACKGROUND

The earliest possible description of GD is in the *Thesaurus of the Shah of Khwarazm,* written around 1110 AD.[1] The first credited description of GD is that of Caleb Parry, who in 1825 described five patients with goiter and palpitations, including exophthalmos in one case.[2] Ten years later, Robert Graves identified three patients with tachycardia and goiter and a fourth who also had exophthalmos.[3] The other major name in the early history of GD is Carl Adolph von Basedow, who in 1840 described a syndrome comprising the "Merseburg triad" of exophthalmos, goiter, and palpitations; two of his patients also had pretibial myxedema.[4] Given this more comprehensive description, the condition was known initially as Basedow's disease, but the eponym honors finally went to Graves, whose textbook of medicine was popular.

Möbius was the first to identify that a thyroid disorder was central to GD, in 1886. Later work focused on the putative role of a thyrotropic pituitary factor with exophthalmic effects, but the appearance of GO in a patient with a total hypophysectomy finally demolished the pituitary theory of GO, although it remained reasonable to postulate that the thyroid overactivity in GD was secondary to pituitary overproduction of such a factor. However, by the 1950s, TSH had been purified, and it became obvious that excess TSH was not the cause of GD. Purves and Adams noted that TSH did not produce the typical lymphocytic infiltration of the thyroid, and therefore set about testing whether TSH really was elevated in GD by means of a bioassay that measured the *in vivo* release of radiolabelled thyroid hormone from the thyroid of guinea pigs. The serum from one patient with GD produced a release of thyroid hormone that was maximal at 24 hours, totally unlike the 3-hour peak effect of TSH; this new activity was therefore called long-acting thyroid stimulator (LATS).[5] By 1964, Kriss and colleagues had demonstrated that LATS was an IgG antibody, and the autoimmune basis of GD was established.

Initially, thyroidectomy (TX) was the only definitive treatment for GD, an operation rendered safer after the introduction of preoperative treatment with stable iodine in the 1920s. The discovery that thiocyanates had a goitrogenic effect led Astwood to develop antithyroid drugs

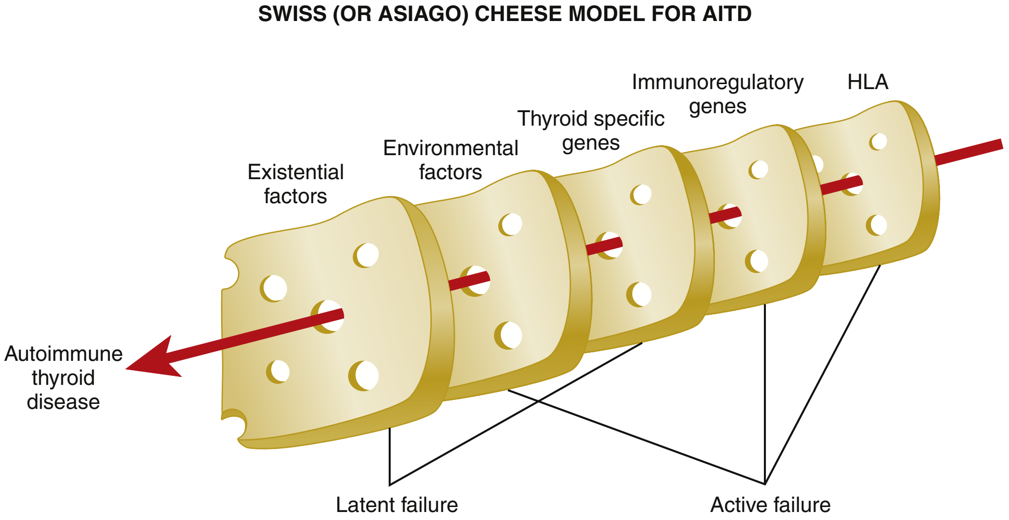

Fig. 71.1 **A model for the emergence of autoimmune thyroid disease.** This shows how the effect of multiple susceptibility factors may align to allow disease to occur in an individual, like the holes in the slices of Swiss cheese: each slice portrayed comprises many individual components, which must line up too. This is based on the well-known Swiss-cheese model for human accidents, which comprises active failures (e.g., pilot error) and latent failures (e.g., poor aircraft maintenance). *AITD*, autoimmune thyroid disease; *HLA,* human leukocyte antigen. (From Weetman AP. The immunopathogenesis of chronic autoimmune thyroiditis one century after Hashimoto. *Eur Thyroid J.* 2012;1:243–250; copyright the author.)

(ATDs), which were first prescribed in the 1940s. The introduction of radioactive iodine (RAI) treatment was based on the pioneering studies with iodine radioisotopes conducted at the Massachusetts Institute of Technology and the Harvard Medical School. Although the first GD patient so treated was in 1941, definitive publication was delayed until after the end of World War II.

ETIOLOGY

For GD to occur, a combination of genetic and environmental factors, working with a background of existential factors such as age, parity, and sex, have to interact in a favorable way to overcome the normal immunoregulatory mechanisms that prevent autoimmunity. This interaction can be thought of as analogous to the Swiss-cheese model for the multilayered causation of accidents (Fig. 71.1). Such a multifactorial model is typical for most autoimmune disorders. The sharing of similar genetic factors predisposing to autoimmunity helps to explain why around 20% of patients with GD have another organ-specific or non-organ-specific autoimmune disease.[6] Patients may also have a family history of various autoimmune problems besides those affecting the thyroid gland. The complexity involved, whereby the same disease may be the result of multiple combinations of susceptibility factors, helps explain why the phenotypic features of GD are diverse. As a simple example, smoking is associated with GD, but the association with GO is even stronger.

Genetic Factors

The role of heredity in GD was initially demonstrated by studies showing a higher frequency of autoimmune thyroid disease or thyroid antibodies in family members of patients with GD. A number of patterns of inheritance and candidate genes have been suggested, but ascertainment artifacts and the drawbacks of underpowered genetic association studies have produced many inconsistencies in results. Meticulous monozygotic twin studies have shown a concordance rate of only around 35% for GD, much lower than was previously thought.[7]

Attempts to understand which genes contribute to GD have typically used either a candidate gene approach, in which the frequency of polymorphisms in a possible candidate gene is determined in a cohort of patients and controls, or genome-wide association studies. The latter have the advantage of being hypothesis-free, thus potentially providing novel insights in etiology, but they demand huge numbers of patients to achieve sufficient statistical power. The susceptibility genes solidly identified so far in thyroid autoimmunity can be broadly classed as those that regulate the immune response and those that are thyroid-specific and thus increase target organ risk.

Immunoregulatory Genes. The first candidate genes to be studied, and the most important susceptibility genes that have been recognized so far, lie in the major histocompatibility complex (MHC), also known as the HLA (human leucocyte antigen), region in humans. Broadly speaking, these genes control the immune response at the level of antigen presentation. Class I HLA molecules, which present endogenous antigens (including those generated by intracellular viruses), are found on the surface of almost all cells and are involved in several immune responses, including cytotoxicity. Class II HLA molecules are expressed by antigen-presenting cells (APCs) and initiate antigen-specific stimulation of helper T-cells.

A consistent association has long been known to exist between the serologically-defined class II specificity HLA-DR3 and GD in Caucasians, with a relative risk of 2 to 3, but more detailed analysis has shown that the strongest association in this population is with the HLA class I allele HLA-C*07.[8] Molecular fine mapping has confirmed that polymorphisms in multiple HLA class I and class II genes independently contribute to disease risk, and this risk appears to be higher in Japanese patients than in European or other East Asian populations.[9] In Han Chinese, different HLA class I and II polymorphisms are associated with GD, but the majority of the risk is from three alleles encoding four amino acid changes, and these alleles may help determine the responsiveness of GD to treatment.[10] Together with many other studies, these results demonstrate a role for both the endogenous and exogenous antigen presentation pathways in determining susceptibility to

GD and show that their etiological role is heavily dependent on the ethnic background of the population, through interaction with other genetic or environmental factors.

The low relative risk conferred by HLA alleles obviously implies the existence of other susceptibility loci. Many candidates have been tested, including genes that encode immunoglobulins, T-cell receptors, and various cytokines, but the first robust association to be identified outside the HLA region was with two linked polymorphisms of the cytotoxic T-lymphocyte antigen-4 (*CTLA-4*) gene, which contribute to both GD and autoimmune hypothyroidism and confer a relative risk of around 2.[11] The CTLA-4 (or CD152) protein is expressed by T-cells and has a critical role in immunoregulation; engagement of CTLA-4 results in T-cell anergy, thus terminating immune and autoimmune responses. Additional polymorphisms in protein tyrosine phosphatase, nonreceptor type 22, *CD40*, and *CD25*, all of which are involved in T-cell regulation, contribute modestly to susceptibility to GD, as well as to many other autoimmune disorders.[11] Using a custom-made single-nucleotide polymorphism array of 186 loci known to be involved in susceptibility to other immune-mediated diseases, seven additional loci for both GD and Hashimoto thyroiditis (HT) have been identified.[12] The same loci have been associated with type 1 diabetes and rheumatoid arthritis, which have an increased prevalence in GD patients. Given the scale of the entire genome and the establishment of ever greater databases, the number of susceptibility loci involved in the etiology of GD looks set to expand much further.

The Thyroid-Stimulating Hormone-Receptor Gene. The genes considered previously are involved in the normal immune process and could exert their effects at the initiation of autoimmunity, through effects on central or peripheral tolerance, or they could vary the intensity of an established autoimmune process. None is specific for GD. In contrast, polymorphisms in the *TSH-R* gene, confirmed as a susceptibility locus for GD but not HT, represent the influence of a tissue-specific gene.[13] In families with an immunogenetic predisposition to developing thyroid autoimmunity, *TSH-R* polymorphisms may be important in determining which members will go on to develop GD rather than HT. It is unclear how these *TSH-R* polymorphisms predispose to GD, but this could be through (1) a less tolerogenic TSH-R being expressed in the thymus, leading to failure of central tolerance, or (2) coding for the increased release of soluble TSH-R fragments, which stimulate the autoimmune response (see later).

Environmental Factors

Iodine and Selenium. Several dietary factors have been implicated as risk factors for the development of both GD and HT. An increase in thyroid autoantibodies and HT has been observed in several populations after instituting iodination programs, and increased dietary iodine may exacerbate experimental disease in animal models of HT, suggesting that iodine has an immunological effect that enhances the thyroid autoimmune response in general.[14] Such an effect of iodine may be owing to altered immunogenicity of the thyroid autoantigen thyroglobulin, or excessive iodine may have a role in the intrathyroidal generation of toxic metabolites, leading to tissue damage. The specific situation in GD is complicated by the Jod–Basedow phenomenon, which is the stimulatory biochemical effect of iodine on thyroid hormone synthesis, especially in the presence of iodine deficiency. This phenomenon is demonstrated by the transient rise in both GD and toxic multinodular goiter after iodine supplementation.[15]

Selenium is found in all three deiodinase enzymes and in other proteins that protect thyroid cells from oxidative injury. Much attention has been paid recently to a possible role of selenium deficiency in autoimmune thyroid disease. So far, variable results have come from measuring selenium intake levels and conducting disease association studies, which in any case cannot directly show causation. There is also a lack of convincing data from selenium supplementation trials, which are heterogeneous and generally do not account for individual variation in dietary selenium intake. So far as GD specifically is concerned, a detailed analysis of existing trials has shown a possible beneficial effect of additional selenium in the rate at which ATD treatment restores euthyroidism, although any long-term effect remains to be demonstrated, and a single randomized control trial showed that selenium may have clinical benefit in mild GO.[16]

Infection. No convincing evidence has indicated a role for infection in GD. An association has been proposed between *Yersinia* infection and GD, and *Yersinia* contains proteins that mimic TSH-R immunologically at the level of TSH-R antibody (TSH-R–Ab) binding. The importance of any such effect seems minimal at best, given the relative frequencies of GD and *Yersinia* infection and the fact that molecular mimicry as a cause of autoimmunity is far more likely to operate at the level of T-cell rather than B-cell epitopes.[14] Hepatitis C is the only infectious agent that has been reliably implicated in the development of HT, but does not appear to be associated with GD. Indeed, epidemiologic studies suggest that inferior levels of prosperity and hygiene, with a consequently greater risk of infections in childhood, may actually protect against the development of thyroid autoimmunity.[17] Such an effect may be mediated by the response to infections skewing the immune system away from proautoimmune T-cell responses during development, the so-called hygiene hypothesis.

Stress. A number of retrospective studies have identified stress during the year before the initial presentation as an important risk factor for GD, but all such surveys suffer from potential flaws in their dependence on recall, as well as other sources of bias, and prospective studies are missing, owing to their difficulty.[18] Any effect of stress presumably results from the neuroendocrine responses to it that alter the regulation of autoreactive lymphocytes. Attacks of allergic rhinitis and elevated serum IgE concentrations (denoting an atopic diathesis) are associated with increased risk of relapse in those with treated GD, perhaps because of the pattern of cytokines produced by the immune system during an allergic episode also exacerbates autoimmunity.[19]

Smoking and Alcohol. Smoking is associated with increased susceptibility to GD, especially in women, with an overall relative risk of around 2: the risk is dose-dependent and disappears if smoking is stopped for several years.[20] The development of GO is even more strongly associated with smoking. On the other hand, alcohol consumption is a dose-dependent protective factor, an effect that is independent of the type of alcohol consumed, sex, iodine intake, and smoking behavior.[21] The reason for these effects is unknown, although smoking can alter normal thyroid function, and alcohol is protective in other autoimmune disease like rheumatoid arthritis.

Drugs. Exogenous cytokines given in massive doses therapeutically, particularly interferon (IFN)-α, exacerbate preexisting thyroid autoimmunity and lead in predisposed individuals to the development of HT, destructive thyroiditis causing transient thyrotoxicosis, and, much less commonly, GD.[22] Other immunologically active drugs can also cause GD. Alemtuzumab is a lymphocyte-depleting monoclonal antibody used to treat multiple sclerosis, and autoantibody-mediated diseases including GD may develop during the phase of immune reconstitution that follows treatment (see later).[23] Immune checkpoint inhibitors are increasingly being used as anticancer treatments. These drugs include CTLA-4 blockers (such as ipilimumab) and programmed death protein 1 blockers (such as pembrolizumab and nivolumab), which enhance T-cell–mediated immunity against tumors and, as a side effect, can induce HT or, rarely, GD.[22] Distinguishing the precise cause of thyrotoxicosis (destructive thyroiditis or GD) in all of these drug-related settings requires care to ensure optimal treatment.

Existential Factors

By far the biggest risk factor for developing GD is being female (as with most autoimmune diseases), with a 5- to 10-fold higher frequency in women. In contradistinction to HT, GD is more common in Black and Asian/Pacific Island people than in White people.[24] Age is also important, as the disease is rare in children, peaking in incidence between the ages of 40 and 50 years. There is a well-established pattern of postpartum occurrence of GD or exacerbation of preexisting GD in the year after delivery, akin to the pattern seen in postpartum thyroiditis, and women below 40 years old who have had live pregnancies or induced abortions are at increased risk of GD in the years after the postpartum period.[25] These effects may be related to reconstitution of the immune system after the alterations in immunoregulation during pregnancy, which ensure maternal tolerance to the fetal semiallograft. Microchimerism, caused by the transfer of fetal cells bearing paternal antigens at delivery and leading to the exacerbation of any ongoing autoimmune response, has also been implicated.

KEY POINTS

- The biggest risk factor for developing Graves disease is being female, with a 5- to 10-fold higher frequency in women.

PATHOLOGY

The thyroid is typically diffusely enlarged, with an increase in vascularity. Untreated GD is practically unseen histologically nowadays, as patients are rendered euthyroid before surgery to ensure their safety, and the typical features are attenuated by ATDs. The thyroid follicles are both hypertrophied and hyperplastic, with columnar epithelium that is often folded into the follicular lumen. New small follicles are formed containing scant colloid. There are varying degrees of lymphocytic and plasma cell infiltration, but, unlike HT, the generation of germinal centers is uncommon. Rarely lymphoid hyperplasia may also occur in the lymph nodes, thymus, and spleen; as with the thyroid lymphocytic infiltrate, these manifestations reverse with ATD treatment. Cases of unnecessary thymectomy have resulted from ignorance of these features.

PATHOGENESIS

GD results from the action of thyroid-stimulating antibodies (TSAbs) that bind to and activate the TSH-R. The primary role of TSAbs is most clearly shown by the occurrence of neonatal GD in the newborn infants of mothers who have a high circulating concentration of these antibodies; the infants' disease remits as the level of placentally transmitted maternal antibody declines. TSH-mediated activation of the TSH-R is characterized by a biphasic regulatory mechanism, which prevents overstimulation of the thyroid, whereas TSAb binding appear to show a monophasic effect, thus allowing chronic activation.[26] However, the degree of hyperthyroidism does not exactly correlate with the measured serum level of TSAb; some patients fluctuate between hyperthyroidism and hypothyroidism because of the simultaneous presence of TSH-R–Ab that block the receptor, and in around 15% of patients treated with ATDs, permanent hypothyroidism supervenes years later, indicating the concurrence of the same kind of tissue-destructive mechanisms that cause autoimmune hypothyroidism. Besides causing hyperthyroidism, TSAb also mediate goitrogenesis and increase the vascularity of the Graves thyroid by enhancing local expression of vascular endothelial growth factor and its receptor.

KEY POINTS

- Graves disease is caused by stimulatory autoantibodies that mimic the action of thyroid-stimulating hormone (TSH) by binding to and activating the autoantigen TSH receptor.

The Role of Thyroid-Stimulating Hormone-Receptor Autoantibodies

Thyroid-Stimulating Hormone-Receptor as an Autoantigen. The TSH-R is a member of the G protein-coupled receptor family; activation of the receptor by TSH or that subset of TSH-R–Ab with stimulatory activity leads to intracellular signaling via the cyclic adenosine monophosphate pathway, although other signaling pathways are activated at high ligand concentrations and by nonstimulating TSH-R–Ab.[27] The receptor is a 744–amino acid glycoprotein with an apparent molecular weight of 95 to 120 kD, depending on glycosylation. It has an extracellular domain, the A subunit, with leucine-rich repeat domains and a hinge region to which TSH and TSH-R–Ab bind, linked via a C peptide region to the B subunit, which comprises a looped transmembrane domain and an intracellular signaling domain[28] Uniquely for a G protein-coupled receptor, the TSH-R is cleaved during posttranslational processing at sites in the hinge region; further reduction of disulfide bonds leads to shedding of the A subunit from the thyroid cell surface. The soluble A subunit that is formed binds TSAb more strongly than the holoreceptor, and this is an important factor in the induction and affinity maturation of TSAb.[28] The enzyme responsible for TSH-R cleavage has not been identified but could have a critical pathological role in GD through regulation of autoantigen production. The extrathyroidal expression of TSH-R, particularly in the orbit, may serve to provide a cross-reactive autoantigen crucial to the complications of GD.

TSAb are high affinity and usually show restriction to the κ light-chain and the IgG1 subclass, implying that they originate from only a small number of B-cell clones. In turn, this indicates that clinical disease manifests itself quickly once the autoimmune process begins in GD, in contrast to the much slower progression of autoimmune hypothyroidism. B-cell epitopes on the TSH-R are generally conformational and discontinuous. The exception is a set of linear hinge region epitopes recognized by "neutral" TSH-R–Ab (Table 71.1), which occurs in some patients with GD. These antibodies may not actually be pathologically neutral, as they can induce thyroid cell apoptosis and alter posttranslational modification of the TSH-R *in vitro*.[27] Patients with GD may also have TSH-R–Abs that can block rather than stimulate the receptor, albeit at a level where the stimulating effect of TSAb supervenes; blocking TSH-R–Abs are more commonly found in HT. The characterization of B-cell epitopes made possible with the development of human monoclonal TSH-R–Abs has shown a greater overall similarity of binding sites for blocking and stimulatory antibodies than had previously been suspected, but there is still considerable heterogeneity in the detailed pattern of epitope recognition by TSAb, which is likely to determine the ultimate severity of clinical presentation. The antibody response to the TSH-R in GD is therefore complex and differs both between patients and in the same patient over time. In some patients, fluctuation in the relative proportion of the two functional types of TSH-R–Abs may produce a confusing clinical picture

TABLE 71.1 Classification of Main Thyrotropin Receptor Antibodies

Antibody	Assay
Long-acting thyroid stimulator	Original description of TSH-R antibodies; used bioassay in whole mouse to assess effects of stimulator antibodies on radioiodine release
TSAb	Bioassay; usually measurement of cAMP production by primary cultures of thyroid cells, thyroid cell lines, (e.g., FRTL-5), or TSH-R-transfected eukaryotic cells
Thyroid-blocking antibodies	Bioassay; measurement of inhibition of cAMP production after TSH-mediated stimulation of the TSH-R; may operate at the level of TSH binding or receptor signaling
TSH binding-inhibiting immunoglobulins (TBII)	Measurement of inhibition by patient antibodies of labeled TSH or labeled monoclonal TSH-R antibody binding to solubilized or recombinant TSH-R; unable to define functional activity
Neutral TSH-R antibodies	Detected by assays with TSH-R hinge region linear peptides; may not be TBII-positive, and no demonstrable effect on cAMP production

cAMP, Cyclic adenosine monophosphate; *FRTL*-5, Fischer rat thyroid line; *TSAb*, thyroid-stimulating antibodies; *TSH*, thyroid-stimulating hormone; *TSH-R*, thyroid-stimulating hormone receptor.

of alternating hyperthyroidism and hypothyroidism, and such fluctuation also may occur after pregnancy.[29]

Assays for Thyroid-Stimulating Hormone-Receptor–Autoantibodies. The nomenclature of TSH-R–Abs can be confusing because of the different names given to the various assays, which have been used in measurement; a summary of these assays is shown in Table 71.1. In essence, demonstrating the true functionality of any TSH-R–Ab requires the use of highly sensitive and specific bioassays that measure activation of the receptor *in vitro*. Such assays have been vital research tools but may be difficult to standardize and maintain in nonexperienced laboratories. Measurement of simple TSH-R binding by an antibody is available in all routine labs and is easier to perform using TSH-binding inhibitor immunoglobulin (TBII) assays; these are commercially available and serve well for clinical purposes, as the result can be interpreted in relation to the patient's presentation. For instance, biochemical thyrotoxicosis and a positive TBII result indicate that the antibodies are most likely TSAbs, and the patient has GD, whereas the same positive TBII result in a hypothyroid patient presenting with HT indicates that the TBII assay is most likely detecting blocking TSH-R–Abs.[29] Current TBII assays have sensitivities and specificities in excess of 95%.

Other Autoantibodies. Thyroglobulin and thyroid peroxidase antibodies occur up to 80% of GD patients. Up to one-third of GD sera contain antibodies that inhibit Na^+/I^- symporter mediated iodide uptake *in vitro*. Antibodies to pendrin, an apical protein responsible for mediating iodide efflux into the follicular lumen, occur in a smaller percentage of patients. All these autoantibodies are also found in autoimmune hypothyroidism and mark the presence of an underlying thyroiditis accompanying the development of TSAbs in GD.

The Role of Cellular Immunity

Self-Tolerance and Autoimmunity. Although GD is an autoantibody-mediated disorder, B-cells only produce antibodies after differentiation into plasma cells, a process that is regulated by cytokines and CD40/CD40 ligand interaction with an activated helper $CD4^+$ T-cell. Activated $CD4^+$ T-cells can follow two broad pathways of function, depending on their pattern of cytokine secretion. Type 1 helper T (Th1) cells mediate delayed-type hypersensitivity responses, essential to the kind of destructive process seen in most organ-specific endocrinopathies, whereas type 2 helper T (Th2) cells promote antibody production. Although this Th1/Th2 paradigm has been useful in murine immunology, many helper T-cells cannot be so neatly classified in humans.

TABLE 71.2 Mechanisms for Maintaining Nonresponsiveness of Autoreactive T-Cells to Target Tissues

Mechanism	Reversibility
Thymic Presentation of Self Antigens (Central Tolerance)	
Deletion	No
Anergy	Yes
Peripheral Tolerance	
Deletion	No
Anergy	Yes
Clonal ignorance	Yes
Immunologic privilege at the target site (e.g., cornea)	Yes
Active Suppression	
Cytokine network	Yes
T regulatory (Treg) cells	Yes

The immune system exists to eliminate foreign antigens but must remain tolerant of autoantigens. Self-tolerance depends critically on the absence of effective autoreactive T-cells. During development, the thymus is mainly responsible for eliminating autoreactive T-cells (clonal deletion) and for positively selecting appropriate T-cells to constitute the immune repertoire.[30] These processes depend on the presentation of endogenous peptides by thymic APCs to the naïve T-cell repertoire. Rare mutations in the autoimmune regulator gene that prevent such presentation of self peptides within the thymus give rise to autoimmune polyglandular syndrome type 1, which may include HT amongst its more usual manifestations. GD is unusual in this syndrome, suggesting additional pathways for intrathymic TSH-R presentation.

We now know, particularly from experiments with transgenic mice, that individual mechanisms for ensuring self-tolerance are never completely successful. In particular, the thymus only manages to prune, rather than eliminate, the autoreactive T-cell repertoire, and so such T-cells are present in all healthy individuals, although held in various states of nonreactivity to self by a number of checkpoints (Table 71.2). Tolerance to a self antigen can be broken at one or more of these controlling points, resulting in autoimmune disease if the response is sufficiently vigorous, and each point may be influenced by both genetic and environmental factors. The following have all been implicated in autoimmunity:

1. An excessive number of autoreactive T-cells may not be deleted or rendered anergic in the thymus (e.g., through inheritance of particular genes).

2. T-cells that escape thymic tolerance may fail to be deleted or rendered anergic in the periphery (e.g., because of abnormal provision of costimulatory signals; see later).
3. Failure of immunologic privilege may occur (e.g., in the cornea).
4. Molecular mimicry may occur with cross-reactive exogenous antigens, inducing a response against a normally "silent" autoantigen (e.g., myocarditis after streptococcal infection).
5. T regulatory (Treg) cells may not function adequately (see later).

There is no clear evidence for failure of immune privilege or the operation of molecular mimicry in GD, but the other mechanisms play a role, although the degree to which each is involved is unclear. Some of the genes associated with GD described earlier may alter intrathymic deletion, especially through thymic TSH-R expression, and the role of Treg cells is considered later. Regarding peripheral tolerance (point 2), only APCs normally express class II HLA molecules, but thyroid cells express class II molecules when stimulated by IFN-γ secreted by any thyroidal T-cells, for instance during an episode of viral thyroiditis. Unlike APCs, however, thyroid cells do not express the necessary costimulatory signals to activate naïve T-cells, and, in this setting, such T-cells are instead rendered anergic.[31] The situation differs when a T-cell has been previously activated: a costimulatory signal is then no longer required, and T-cell stimulation will occur. Thus, HLA class II expression by thyroid cells may be a means of ensuring peripheral T-cell tolerance under normal circumstances, but such expression may exacerbate already established thyroid autoimmunity (Fig. 71.2).

Insights From Animal Models. It is striking that, in contrast to HT, no spontaneous animal model of GD has been found. Such restriction may be because (1) the necessary predisposing genetic and environmental factors are exclusively human, or (2) the TSH-R is uniquely autoantigenic in humans. Attempts to create an induced animal model of GD with TSH-R immunization have also been frustrating, with initial experiments resulting in thyroiditis and blocking TSH-R–Abs. Hyperthyroidism and stimulating TSH-R–Ab can be induced in rodents by immunization with fibroblasts expressing MHC class II molecules and the human TSH-R, or with plasmid or adenovirus vectors encoding the holoreceptor or the A subunit.[32] NOD.H2h4 mice have spontaneous background HT, and using this strain to create transgenic animals with intrathyroidal expression of the human TSH-R A subunit results in the spontaneous development of human-specific TSAbs; similar expression of the mouse TSH-R A subunit does not result in TSH-R–Abs.[33] These results indicate that the human TSH-R A subunit may indeed be uniquely autoantigenic, but also show the importance of the necessary genetic background to initiate disease. This animal model has also provided evidence that the level of intrathymic expression of the TSH-R A subunit is critical in determining whether autoimmunity or central tolerance is induced.[34]

T-Cell Responses. Examining TSH-R–specific T-cell function in GD is currently prevented by the low number of such cells, their predominantly intrathyroidal location, and the distorting effects of ATDs on the autoimmune response. Many studies have used the circulating T-cell population, which may have little or no relevance to what is happening within the thyroid lymphocytic infiltrate. Various abnormalities in the phenotype of circulating T-cells have been described, such as a reduction in CD8$^+$ T-cells and an increase in activated HLA-DR$^+$ T-cells, but these are not specific to GD. Circulating T-cells respond to multiple T-cell epitopes on the TSH-R in GD. The intrathyroidal T-cells are a mix of CD4$^+$ and CD8$^+$ populations, the latter presumably contributing to the destructive thyroiditis that may eventually supervene. Attempts have also been made to understand the pattern of cytokines secreted in GD, with the overly simplified view that this is likely to be a Th2-mediated disorder. However, the predominance of the IgG1 subclass in TSAb indicates a robust Th1 type response, as does the pattern of chemokine expression, which is important in the active phase of disease.[35] No distinct Th1 or Th2 pattern of response of cytokines has been observed within the thyroid in GD, and some cytokines are derived from the thyroid cells themselves or from other immune system cells, including the proinflammatory Th17 T-cell subset.[36,37]

Fig. 71.2 Alternative outcomes after major histocompatibility complex (*MHC*) class II expression by thyroid cells. Naïve T cells require costimulation for activation, and anergy can be induced by interaction with the MHC class II molecule/antigenic epitope alone (upper panel, peripheral tolerance). If T cells receive prior costimulation from classic antigen-presenting cells (*APCs*), class II expression by thyroid cells can enhance the T-cell response *(lower panel)*. *IFN*, Interferon. (From Jameson LJ, De Groot LJ, de Kretser DM, et al. *Endocinology: Adult and Pediatric,* 7th ed. Philadelphia: Elsevier; 2016.)

The levels of CD4$^+$FOXP3$^+$ "natural" Treg cells are either normal or lowered in the circulation of untreated patients with GD; abundant natural Treg cells can be detected in the thyroid infiltrate but seem to have lowered function.[37] Once activated, Treg cells exert their effects without antigen restriction, and so it is the intrathyroidal population that is most likely to be critical to pathogenesis. There is good evidence from animal models that systemic Treg cell depletion leads to the development of experimental HT and hypothyroidism, but the effects of such depletion on experimental GD are not known.[14] With the continuing description of new types of regulatory cells, which now encompass subpopulations of B-cells, CD8+ cells, and Th1, Th2, and Th17 cells with differing immunoregulatory capacities,[38] it is evident that the control of autoimmune T-cell responses in GD is at present poorly understood. MicroRNAs (noncoding small RNA molecules) regulate normal gene expression, including genes involved in the innate and adaptive immune response. Recently, dysregulation of specific microRNAs has been implicated in autoimmunity, and a signature profile of microRNAs within the thyroid has been identified that shows associations with the severity of GD, the response to treatment, and the occurrence of GO.[39] This area offers the potential of developing new insights into pathogenesis, as well as novel biomarkers and even therapies.

Immune Reconstitution and Graves Disease. GD (as well as HT and a spectrum of autoimmune disorders) has been reported in three particular settings of immune reconstitution after a period of induced lymphopenia.[23] First, bone marrow transplantation using a donor who has had GD may transfer the disease to the recipient. This is primarily the result of adoptive immunity transferring autoreactive lymphocytes, although there may be an additional role for disordered immunoregulation secondary to graft-versus-host disease. Second, alemtuzumab is a humanized monoclonal antibody against CD52 expressed by lymphocytes and macrophages that rapidly depletes T-cells and is mainly used for active relapsing-remitting multiple sclerosis. GD occurs in up to one-third of such patients during the phase of naïve T-cell expansion, which occurs around 18 months after therapeutic lymphocyte depletion. Fluctuating levels of TSAbs and blocking TSH-R–Abs occur in 20% of the Graves cases, and the disease may be quite resistant to treatment. Finally, GD occurs in up to 3% of patients with human immunodeficiency virus infection given highly active antiretroviral therapy, again during the phase of T-cell expansion. The mechanisms responsible for reconstitution GD are at present unclear but may include dysregulation of Treg function and the effects of interleukin-21, a pleiotropic cytokine that can promote autoimmune responses through its effects on Th17 and B-cell activation.[14]

CLINICAL SPECTRUM

Signs and symptoms include features that are common to any cause of thyrotoxicosis (Table 71.3), as well as those specific for GD.[40] The clinical presentation depends on the severity of thyrotoxicosis, the duration of the disease, individual susceptibility to excess thyroid hormone, and the age of the patient. In the elderly, features of thyrotoxicosis may be subtle or masked, and patients may present mainly with fatigue and weight loss, leading to apathetic hyperthyroidism. Thyrotoxicosis may cause unexplained weight loss, despite an enhanced appetite, and is because of the increased metabolic rate. Weight gain occurs in 5% to 10% of patients because of increased food intake. Other prominent features include hyperactivity, nervousness, and irritability, ultimately leading to a sense of easy fatigability in some patients. Insomnia and impaired concentration are common; apathetic thyrotoxicosis may be mistaken for depression in the elderly.[41]

In GD, the thyroid is diffusely enlarged to two to three times its normal size (Table 71.4). The consistency is firm, but less so than in multinodular goiter. There may be a thrill or bruit because of the increased vascularity of the gland and the hyperdynamic circulation. The most common cardiovascular manifestation is sinus tachycardia, often associated with palpitations and sometimes because of supraventricular tachycardia. The high cardiac output produces a bounding pulse, widened pulse pressure, and an aortic systolic murmur, and can lead to worsening of angina or heart failure in the elderly or those with preexisting heart disease.[42] Atrial fibrillation is more common in patients older than 50 years. Treatment of the thyrotoxic state alone reverts atrial fibrillation to normal sinus rhythm in fewer than half of patients, suggesting the existence of an underlying cardiac problem in the remainder.

TABLE 71.3 Causes and Differential Diagnosis of Hyperthyroidism

Primary hyperthyroidism

- Graves disease
- Toxic multinodular goiter
- Toxic adenoma
- Amiodarone, iodine excess
- Ingestion of excess thyroid hormone (thyrotoxicosis factitia) or thyroid tissue
- Subacute thyroiditis
- Silent thyroiditis
- Activating mutation of the thyroid-stimulating hormone receptor (autosomal dominant)
- Struma ovarii
- Functioning thyroid carcinoma metastases

Secondary hyperthyroidism

- Thyroid-stimulating hormone–secreting pituitary adenoma
- Thyroid hormone resistance syndrome
- Chorionic gonadotropin–secreting tumors
- Gestational thyrotoxicosis

TABLE 71.4 Signs and Symptoms of Graves Hyperthyroidism

Symptoms

- Hyperactivity, irritability
- Heat intolerance and sweating
- Palpitations
- Dysphoria
- Fatigue and weakness
- Weight loss with increased appetite
- Diarrhea
- Polyuria
- Oligomenorrhea, loss of libido

Signs

- Tachycardia
- Atrial fibrillation in the elderly
- Tremor
- Goiter
- Warm, moist skin
- Muscle weakness, proximal myopathy
- Lid retraction or lag
- Exophthalmos
- Gynecomastia

The skin is usually warm and moist, and the patient complains of sweating and heat intolerance, particularly during warm weather. Palmar erythema, onycholysis, and ,less commonly, pruritus, urticaria, and diffuse hyperpigmentation may be evident. Hair texture may become fine, and a diffuse alopecia occurs in up to 40% of patients, persisting for months after restoration of euthyroidism. Fine tremor is a very frequent finding, best elicited by asking patients to stretch out the fingers and feeling the fingertips with the palm. Common neurologic manifestations include hyperreflexia, muscle wasting, and proximal myopathy without fasciculation. Chorea is a rare feature. Thyrotoxicosis is sometimes associated with a form of hypokalemic periodic paralysis; this disorder is particularly common in Asian males with thyrotoxicosis. Gastrointestinal transit time is decreased, leading to increased stool frequency, often with diarrhea and occasionally mild steatorrhea. Women frequently experience oligomenorrhea or amenorrhea; in men, there may be impaired sexual function and, rarely, gynecomastia. The direct effect of thyroid hormones on bone resorption leads to osteopenia in longstanding thyrotoxicosis; mild hypercalcemia occurs in up to 20% of patients, but hypercalcuria is more common. There is a small increase in fracture rate in patients with a previous history of thyrotoxicosis.

KEY POINTS

- Graves disease is characterized by autoimmune-induced hyperthyroidism, a diffusely enlarged thyroid gland, and, in around 30%–40% of patients, orbitopathy.

DIAGNOSIS

Serology

Serum TSH measurement has the highest sensitivity and specificity of any single blood test used in the evaluation of suspected hyperthyroidism and is used as initial screening.[43-45] However, when hyperthyroidism is strongly suspected, diagnostic accuracy improves when both a serum TSH and free T4 are assessed at the time of the initial evaluation. In overt hyperthyroidism, both serum free T4 and T3 concentrations are elevated, and serum TSH is suppressed; however, in subclinical hyperthyroidism, serum total T4 and free T4 levels can be normal, with an undetectable or low serum TSH. Finally, measurement of serum T3 is helpful, as isolated T3 elevation ("T3-toxicosis") is observed in several patients with GD of recent onset. TSH-R–Abs are specific biomarkers for GD.[46-48] The likelihood that patients have GD is 1367- to 3,420-fold greater if they are TSH-R–Ab–positive than if they are TSH-R–Ab–negative.[46] Most immunoassays today use a competitive binding assay and measure TBIIs. Binding assays only report the presence or absence of TSH-R–Abs and their concentrations, rather than their functional activity.[49] A metaanalysis of 21 studies showed that the overall pooled sensitivity and specificity of the serum TSH-R–Ab concentration measured with binding assays were 98 and 99%, respectively.[50] In contrast, the highly sensitive cell-based bioassays[1-58] exclusively differentiate between the stimulating (TSAb) and TSH-R–blocking antibodies.[59-61] In addition, TSAb is a highly sensitive and predictive biomarker for the extrathyroidal manifestations of GD,[62-68] as well as a useful predictive measure of fetal or neonatal hyperthyroidism.[69,70] Further, the incorporation and early utilization of TSAb into diagnostic algorithms conferred a 46% shortened time to diagnosis of GD and a cost saving of 47%.[71] In summary, the measurement of TSH-R–Ab is a sensitive and specific tool for rapid and accurate diagnosis and differential diagnosis of Graves hyperthyroidism. When technically available, differentiation of TSH-R–Ab functionality is helpful and predictive in GD patients during pregnancy/postpartum, as well as for evaluating extrathyroidal manifestations.

KEY POINTS

- The thyroid-stimulating hormone receptor antibody (TSH-R–Ab), especially the stimulatory TSH-R–Ab, is the serum biomarker of Graves disease; it offers rapid and accurate diagnosis of Graves hyperthyroidism and is very useful for the differential diagnosis of thyrotoxicosis.

Imaging

In addition to thyroid function and TSH-R–Ab determination, most clinicians would request thyroid ultrasound (US) and, less often, isotope scanning.[47] Thyroid US is a convenient, noninvasive, rapid, and accurate tool in the initial work-up of GD patients. It aids in the diagnosis, without exposing the patient to ionizing irradiation, and assists in determining the underlying etiology of thyrotoxicosis and detecting concomitant thyroid nodules.[72,73] A high-frequency linear probe should be used. GD is often, but not invariably, characterized by diffuse thyroid enlargement and by hypoechogenicity, both assessed by US and conventional gray-scale analysis.[74] A color-flow or power Doppler examination characterizes vascular patterns and quantifies thyroid vascularity.[75] The latter is significantly increased in untreated GD and typically shows a pulsatile pattern called "thyroid inferno," (i.e., multiple small areas of increased intrathyroidal blood flow seen diffusely throughout the gland).[76] Typical US patterns combined with positive TSH-R–Ab obviate the need for scintigraphy in the vast majority of cases. However, RAI uptake and/or isotope scintigraphy may be useful in the assessment of patients before RAI treatment, especially when facing coexistent multinodular goiter.[74] In summary, thyroid US, comprising conventional gray-scale analysis and color-flow Doppler examination, is recommended as the imaging procedure to support the diagnosis of Graves hyperthyroidism, while thyroid scan is suggested when thyroid nodularity coexists with hyperthyroidism, and before RAI therapy.

MANAGEMENT

The hyperthyroidism of GD is treated by reducing thyroid hormone synthesis using thionamide ATDs or by reducing the amount of thyroid tissue with RAI treatment or total TX. Overall, the American guidelines[77] have been noncommittal in their approach to selecting an individual therapy and leave this to the patient and their physician after an assessment of individual preferences. In comparison, the European guidelines,[78] although offering "personalized medicine," favor ATDs as the treatment of choice.

KEY POINTS

- The thionamide antithyroid drugs (ATDs) are the most popular treatment for Graves hyperthyroidism, especially for the first onset of the disease.
- Methimazole (MMI) is the preferred ATD worldwide.
- Persistent hyperthyroidism after an 18-month first course of ATD or a relapse of Grave disease are indications for a definitive treatment, (e.g., radioactive iodine (RAI) administration or total thyroidectomy). However, long-term, low-dose MMI administration is a safe, reliable, and low-cost alternative
- *De novo* and/or exacerbation of extrathyroidal orbital disease occurs in 15%–25% of cases post-RAI.

ANTITHYROID DRUGS

ATDs have always been the first-line treatment for GD in Europe and Asia, but RAI was the preferred treatment modality in the United States.[79,80] This has changed dramatically in the last decade, and now ATDs are the most common treatment in the United States; they are used in 58% of patients, followed by RAI in 35%.[81] The reason for this shift away from RAI towards ATDs is the realization that RAI is associated with a definite risk of developing or exacerbating GO.[82,83] Numerous randomized clinical trials and metaanalyses comparing the effects of either RAI therapy or ATDs on the development or progression of GO have shown better outcomes using ATD therapy.[82,84] These differences are largely attributed to adverse effects of RAI on TSH-R autoimmunity, as evidenced by sustained increases in TSH-R–Ab titers after RAI compared with gradual decreases during a prolonged course of ATDs.[85]

The thionamide ATDs are ring-structured sulfur-containing compounds that are thiourea derivatives. ATDs inhibit the organification of inorganic iodine, an early step in thyroid hormone synthesis (Table 71.5). This process is catalyzed by thyroid peroxidase and requires

TABLE 71.5 Mechanism of Action of Thionamide Antithyroid Drugs

- Intrathyroidal inhibition of:
    - Iodine oxidation/organification
    - Iodotyrosine coupling
    - Thyroglobulin biosynthesis
    - Follicular cell growth
- Extrathyroidal inhibition of T4/T3 conversion (propylthiouracil)
- Immunological effects:
    - Direct effects on both intrathyroidal T-cells and human leukocyte antigen class II expression by thyrocytes
    - Increase numbers of suppressor T-cells and decrease intrathyroidal activated T-cells
    - Inhibit proinflammatory mediator release, including oxygen radicals, by thyroid cells

TABLE 71.6 Pharmacology and Pharmacokinetics of Thionamide Antithyroid Drugs

	Methimazole	Propylthiouracil
Absorption	Rapid	Rapid
Bioavailability	~100%	~100%
Peak serum level	60–120 minutes	60 minutes
Serum half-life	6–8 hours	90 minutes

Cross-reaction of AE (%)	13.8	15.2
Compliance	high	fair
Costs	low	moderate

endogenously generated hydrogen peroxide.[86,87] Three ATDs are available: methimazole (MMI), propylthiouracil (PTU), and carbimazole. Carbimazole is not an active drug and is rapidly metabolized in the blood to MMI, with 10 mg carbimazole yielding approximately 6 mg of MMI.[88] PTU, but not MMI, inhibits selenoprotein type I iodothyronine deiodinase, thereby reducing conversion of T4 to T3 in peripheral tissues. The mechanism of inhibition of type I deiodinase appears to be formation of a stable selenyl-sulfide moiety, which prevents the formation of a key selenyl-iodide intermediate.[89] ATDs have direct effects on both intrathyroidal T-cells[90] and HLA class II expression by thyrocytes,[91] as well as on increased numbers of suppressor T-cells and decreased intrathyroidal activated T-cells.[92] These effects are probably secondary to the release of drug action–inhibiting proinflammatory mediators, including oxygen radicals, by thyroid cells. MMI and PTU inhibit leukocyte production of oxygen radicals in a dose-dependent manner[93,94] and accelerate hydrogen peroxide scavenging in cultured thyroid cells.[93]

MMI can be given as a single daily dose, whereas PTU, the least potent ATD with the shortest duration of action, is initiated three times daily (Table 71.6). A PTU dose of 100 mg is equivalent to 5 to 6 mg of MMI (15–20:1). Initial dosing of MMI depends on the severity of hyperthyroidism and is based on the elevation in free T4, using 5 to 10 mg if free T4 is 1 to 1.5 times the upper limit of normal or 20 and 30 mg if free T4 is 2- and 3-fold increased.[77,78] MMI is the preferred ATD because of superior efficacy, the ability to use once daily, and a lower adverse effect profile.[95] Surveys show that less than 5% of endocrinologists choose PTU as the initial ATD.[47,79] However, PTU is still preferred during the first trimester of pregnancy because of a lower prevalence and severity of drug-associated embryopathy compared with MMI,[96] and in the treatment of thyroid storm, where the additional inhibition of T4-to-T3 conversion is critical for early reversal of this disorder.[7] Both MMI and PTU are nearly completely absorbed following oral administration, with peak serum levels obtained within 1 to 2 hours. Each drug is further concentrated within the thyroid. Intrathyroidal MMI levels are approximately 2- to 5-fold higher than peak plasma levels, and the intrathyroidal levels remain high 20 hours after ingestion.[98] Restoration of euthyroidism occurs gradually, as existing thyroid hormone stores are released and T4 is converted to T3 both within the thyroid and in the peripheral tissues.

The optimal duration of ATD therapy is approximately 18 months, with a high recurrence rate after only 6 months and no apparent additional benefit by extending therapy beyond 18 to 24 months.[99] The "block-and-replace" regimen, in which LT4 is added to ongoing ATD therapy, neither enhances the remission rate nor decreases the recurrence of hyperthyroidism.[100] [101] Hence, the evidence-based titration regimen is favored.[77,78] Approximately 50% of patients receiving ATD for 12 to 18 months will enter a period of drug-free remission, with remission rates ranging from 30% to 60%.[102] Although hyperthyroidism subsequently recurs in one-third of patients initially achieving a remission, approximately one in three patients treated achieves permanent remission (i.e., biochemical euthyroidism and negative TSH-R–Ab). Consistent features predictive of remission include TSH-R–Ab titers that normalize on therapy, a small goiter, and lesser degrees of thyrotoxicosis.[103] Features with a negative influence on remission rates include tobacco smoking, age under 30 years, and the postpartum state.[104,105] However, the predictive value of each of these risk factors is too low for accurate assessment of the remission chance before starting ATD in an individual patient. A recent prospective study was able to construct a predictive score by combining a number of independent risk factors. This so-called Graves' Recurrent Events after Therapy (GREAT) score provides a reasonable prediction of recurrent Graves hyperthyroidism after an 18-month course of ATDs.[106] The GREAT score takes into account four baseline characteristics that are already assessed routinely in the work-up of every patient with Graves hyperthyroidism: TSH-R–Ab, free T4, goiter size, and age. Patients for whom the GREAT score falls in class I have a rather high chance of remission (84%), and ATD would be a reasonable option. In contrast, the chance of remission is rather low in GREAT score class III (32%), and TX or RAI might be preferred.

In summary, patients with newly diagnosed GD are treated with ATDs. RAI therapy or TX may be considered in patients who prefer this approach. MMI should be used in every nonpregnant patient who choses ATDs. MMI is administered for 12 to 18 months, then discontinued if the TSH and TSH-R–Ab levels are normal. Measurement of TSH-R–Abs before stopping ATD therapy is recommended, as it aids in predicting which patients can be weaned from the medication, with normal levels indicating a greater chance of remission. Patients with persistently high TSH-R–Ab at 18 months can opt for definitive treatment or continue low-dose MMI therapy.

Adverse Events

Most common adverse events (AEs) ascribed to ATD include minor cutaneous allergic reactions, including rash (3%–6%), pruritis (2%–3%), and urticaria (1%–2%), as well as dyspepsia (3%–4%), nausea/gastric distress (2.4%), and arthralgia (1.6%). Cutaneous reactions to ATDs occur within the first few weeks of therapy.[107] Antihistamine therapy without stopping ATD in patients with mild skin reactions, an alternate ATD in the case of moderate AEs, and avoidance of ATDs in patients with severe cutaneous AE are recommended.[77] Major AEs (Table 71.7) include agranulocytosis, hepatotoxicity, pancreatitis, and vasculitis.[95,108] Agranulocytosis occurs in 0.2% to 0.5% of patients taking ATDs.[109] The onset is abrupt, with high fever and severe pharyngitis. Most cases occur within the first 90 days of treatment.[109] Agranulocytosis is dose-related with respect to MMI,[110], but not PTU. Agranulocytosis is caused by immune targeting of the granulocytic lineage in the bone marrow rather than a direct toxic effect.[111] ATDs are concentrated within granulocytes and metabolized by myeloperoxidase,[112] thus leading to alterations of the cell membrane. Specific HLA alleles in Asian and White persons[113,114] increase susceptibility to ATD-induced agranulocytosis. Management involves broad-spectrum antibiotics and granulocyte colony-stimulating factor.[115] Recovery of white blood cell counts occurs over 7 to 14 days. The mortality rate remains approximately 5%, with older age, comorbidities, and septicemia at the time of diagnosis being risk factors. Because of insufficient evidence and lack of cost-effectiveness, routine white blood cell count monitoring is not recommended.[77,95] PTU-induced vasculitis often occurs after years of treatment and is associated with perinuclear anticytoplasmic neutrophil antibody (ANCA).[116] Vasculitis usually resolves with drug discontinuation, but a few patients have required immunosuppressive therapy and hemodialysis. Routine screening for ANCA positivity is not recommended.[77] Hepatocellular toxicity has been described predominantly with PTU, with a cholestasis picture associated with MMI. This view has been challenged recently.[117,118] Among 71,379 patients newly prescribed ATDs, hepatotoxicity occurred in 0.3% of patients exposed to MMI and 0.15% of those given PTU. MMI and PTU were associated with noninfectious hepatitis in 0.25% and 0.08% of cases, respectively.[117] The rates of cholestasis were similar with PTU and MMI, but the rates of hepatic failure were higher with PTU than with MMI. Guidelines do not recommend routine monitoring of liver function in patients on ATDs. However, patients should be informed about possible hepatotoxicity, discontinue the offending drug, and contact their physician immediately with the onset of jaundice, dark urine, or clay-colored stools. Because up to one-third of patients with thyrotoxicosis have baseline transaminase elevation, liver function testing before starting ATDs is warranted, and ATDs should be avoided if baseline transaminase values are more than 5-fold increased.[77] In summary, patients should be informed of the potential side effects of ATDs and the necessity of informing the physician promptly if they should develop jaundice, light-colored stools, dark urine, fever, pharyngitis, or cystitis. In those cases, a differential white blood cell count and liver function should be assessed.

TABLE 71.7 Adverse Events of Thionamide Antithyroid Drugs

Common (1%–5%)

- Skin rash
- Urticaria
- Arthralgia
- Fever
- Transient mild leukopenia

Rare (0.2%–0.5%)

- Gastrointestinal
- Abnormalities of taste and smell
- Agranulocytosis (within the first 90 days)

Very rare

- Hepatitis (propylthiouracil, PTU)–avoid in children!
- Vasculitis, lupus-like (PTU)
- Aplastic anemia (PTU)
- Thrombocytopenia (PTU)
- Hypoglycemia (antiinsulin antibody) (PTU)
- Cholestatic jaundice (methimazole)
- Pancreatitis (?)

Pregnancy

GD affects approximately 0.1% of pregnancies[119] and is associated with a significantly increased risk of adverse outcomes in mother and child, as well as maternal–fetal complications.[120] Preterm labor, fetal loss, low birth weight, hydrops, pregnancy-induced hypertension, maternal congestive heart failure, and congenital malformations in offspring have been reported. Seizures and neurobehavioral disorders occurring later in life may also be related to fetal exposure to excess maternal thyroid hormones.[121] Thus, ideally, thyrotoxic women are rendered stably euthyroid before attempting pregnancy.

Treatment of GD during pregnancy and in the preconception period poses significant problems regarding indications for treatment, therapeutic options, and use of ATDs. ATDs cross the placenta and may produce fetal–neonatal hypothyroidism and teratogenic effects in the embryo.[122] MMI and PTU have similar kinetics of placental crossing and similar risks of inducing fetal and neonatal hypothyroidism.[123] Both MMI and PTU are associated with teratogenesis.[124,125] MMI-associated birth defects occur at a rate of 3% to 4% (e.g., choanal atresia, esophageal atresia, aplasia cutis), especially if the fetus is exposed during gestational weeks 6 to 10.[96,126] The risk of birth defects with PTU is 2% to 3%, although they are less severe (e.g., renal cysts, preauricular and branchial sinus or fistula).[127] Therefore, ATDs are ideally avoided in the first trimester of pregnancy, especially in the critical gestational weeks 6 to 10. This is feasible if hyperthyroidism is mild; however, ATDs are the mainstay of treatment for clinically significant GD during pregnancy. When necessary, PTU is generally favored, because of lower risk of severe birth defects. In the second and third trimester, given the risk of severe hepatotoxicity with PTU, the recommendations focus on reverting to the use of MMI.[128]

All patients with a history of autoimmune thyroid disease should have their TSH-R–Ab serum levels measured at the first presentation of pregnancy[77,78,119] using either a sensitive-binding or preferably a functional cell-based bioassay, and, if they are elevated, again at 18 to 22 weeks and, if still elevated, again at 30 to 34 weeks of gestation. If the maternal TSH-R–Ab concentration remains high (more than three times the cutoff), monitoring of the fetus for thyroid dysfunction throughout pregnancy is recommended. TSH-R–Abs are monitored in the same manner if the mother has been treated with RAI or TX before pregnancy. When GD is diagnosed before pregnancy and the patient is taking MMI, it should be switched to PTU or withdrawn as soon as pregnancy is confirmed.[119] The risk of relapse after ATD withdrawal in early pregnancy is high in those with high TSH-R–Abs, those who require greater than 10 mg of MMI per day, those with severe GO, and those who have been treated for less than 6 months. When this risk is considered high, then, instead of ATD withdrawal, therapy should be switched to PTU during the first trimester. During pregnancy, the lowest possible dose of ATDs should be given, and the block-and-replace ATD regimen is discouraged. Maternal free T4 and TSH should be measured every 2 weeks after the initiation of therapy and every 4 weeks after achieving the target value. A change from PTU to MMI should be considered if ATDs are required after 16 weeks of gestation. In women on a low dose of MMI (<5–10 mg/day) or PTU (<50–100 mg/day), ATDs may be stopped during gestation before weeks 6 to 10. Lactating women with GD should be offered the same treatments as nonlactating women. MMI is recommended during lactation, given the concerns about PTU-mediated hepatotoxicity.[77,78,119]

Long-Term Antithyroid Drug Therapy

If TSH-R–Abs are negative at the end of 12 to 18 months of ATD therapy, it is reasonable to discontinue ATDs, as the likelihood of remission is relatively high. In contrast, remission is relatively unlikely in the presence of high TSH-R–Ab levels at the end of ATD therapy. High TSH-R–Ab levels after treatment in the presence of normal serum thyroid hormone levels is often referred to as persistent serological hyperthyroidism.[78] This reflects the notion that Graves hyperthyroidism is not really cured as long as TSH-R–Abs are present. Both European and American guidelines acknowledge the feasibility of continuing ATD for a further 12 months if TSH-R–Abs are still high[78] or to proceed with long-term use of a low dose of MMI.[77] Indeed, patients increasingly report a preference for nonablative therapy.[81] The best argument, however, for long-term ATD therapy is a recent prospective randomized clinical trial showing a 4- to 5-fold increased cumulative incidence of relapse of hyperthyroidism in GD patients treated for an average of 19 months (±3 months) with MMI in comparison with a GD group treated for 95 months (±22 months, $P < .001$).[129] Further, there is a lower incidence of AEs on a low (maintenance) dose of MMI,[130] and most cases of agranulocytosis occur within the first 3 months of ATD therapy.[131] Conversely, ATD therapy requires serial reassessment of dosing adequacy, surveillance for possible overtreatment, and monitoring for rare late-occurring AEs related to ATDs.[132] A study comparing 10-year outcomes in patients randomized to either RAI or further ATD therapy after initially failing to achieve a remission on ATDs found that management costs were lower with ATDs, and episodes of hypothyroidism occurred more frequently after RAI than with ATDs. Studies of long-term ATD therapy with a block-and-replace regimen found that 90% of patients stayed continuously euthyroid during a mean follow-up of 6.7 years, with a paucity of ATD-induced AEs.[132] ATD therapy in patients treated for 2 to 11 years and then followed for an average of 4.5 years after stopping ATDs led to a remission rate of 63%.[133] A metaanalysis of patients treated with ATD for a minimum of 2 years found an AE rate of 19.1%, consisting of rash, gastric intolerance, or arthralgia, with only 1.5% of patients experiencing severe AEs.[105] Finally, patients treated with either continued low-dose ATDs or RAI following an initial relapse after ATD therapy showed that low-dose ATDs were associated with better maintenance of euthyroidism, less weight gain, less GO deterioration, and similar quality of life compared with RAI.[134] In summary, if a patient with GD becomes hyperthyroid after completing a first course of ATDs, definitive treatment with RAI or TX is recommended. However, continued long-term low-dose MMI can be considered in patients not in remission who prefer this approach.

Children, Adolescents, and the Elderly

PTU is contraindicated in children and adolescents because of its enhanced hepatotoxicity.[77,78,135] Long-term MMI should be the mainstay of treatment in children with GD. TX is the primary definitive therapy in childhood, but in postpubertal children RAI can be considered. Older patients who have had atrial fibrillation, cardiac failure, or cardiac ischemic symptoms precipitated by hyperthyroidism should undergo definitive therapy, usually RAI.[77,78] Long-term, low-dose MMI is considered a satisfactory treatment for older individuals with mild GD.

Symptomatic Management

Beta-adrenergic blockade is recommended in all patients with Graves hyperthyroidism.[42,136] Propranolol or longer-acting beta-blockers (bisoprolol/atenolol) are useful to control adrenergic symptoms (palpitations/tremor), especially in the early stages before ATDs take effect. High doses of propranolol (40 mg four times daily) inhibit peripheral conversion of T4 to T3.[77,78] Cardio-selective beta-blockers with higher cardioprotective effects and superior prevention of atrial fibrillation are an alternative, especially for patients with asthma. Anticoagulation with warfarin or direct oral anticoagulants should be considered in all patients with atrial fibrillation.[42,46,136]

Subclinical Graves Hyperthyroidism

Subclinical hyperthyroidism is defined as a low TSH and normal thyroid hormone levels in the absence of overt symptoms of hyperthyroidism. Endogenous subclinical hyperthyroidism is associated with increased risk of coronary heart disease mortality, atrial fibrillation, heart failure, fractures, and excess mortality in patients with serum TSH levels less than 0.1 mIU/L.[137-139] In addition, in the presence of TSH-R–Abs indicating "subclinical" GD, the rate of progression to overt hyperthyroidism is up to 30% in the subsequent 3 years.[140] Therefore, treatment of subclinical hyperthyroidism is recommended in GD patients in general and in those older than 65 years, in particular with completely suppressed serum TSH levels.[78] ATDs are the first choice.

RADIOACTIVE IODINE

American Thyroid Association guidelines stipulate that the goal of RAI therapy in GD is to control hyperthyroidism by rendering the patient hypothyroid.[77] Advantages of RAI include avoidance of surgical risk and potential avoidance of hormone replacement therapy. RAI treatment should be considered in the elderly and in those with significant comorbidities, contraindications for surgery, previous neck radiation, small goiters, and limited access to high-volume surgeons.[77] It is contraindicated in pregnancy or in those planning a pregnancy, as well as in those who cannot comply with radiation safety guidelines. RAI should be used with caution in GD, as it can exacerbate GO.[74,78,141] RAI treatment can be considered in the absence of GO and/or in clinically mild, inactive GO in nonsmokers, but it should be avoided in active and moderate to severe GO.[74,77,78] Clinical exacerbation of hyperthyroidism, and even thyroid storm, can occur with RAI, especially in the elderly and in those who have comorbidities that may increase the risk of thyrotoxicosis,[142] including cardiovascular disease, atrial fibrillation, heart failure, pulmonary hypertension, diabetes, renal failure, infection, trauma, or cerebrovascular disease. These patients should be given beta-blockers[42,77,136] and be considered for MMI treatment before and after RAI treatment. In individuals who will benefit from pretreatment with MMI, the recommendation is to give it before RAI but discontinue it 3 days before RAI treatment and then resume 3 days after RAI treatment with a taper, while thyroid function tests should simultaneously normalize. Young, healthy individuals who are clinically well compensated tolerate RAI without pretreatment.[77,78] In patients who are not pretreated, thyroid levels stabilize or decrease in the first month after RAI.

RAI is very effective, provided a sufficient radiation dose is delivered in the thyroid. This can be done equally well by a fixed activity of RAI (^{131}iodine) or by a calculated activity based on thyroid size and thyroid RAI uptake.[77] Balancing rapid relief of hyperthyroidism and postponement of hypothyroidism appears to be an elusive goal. No dose calculation can secure long-term euthyroidism.[78] Many centers therefore have given up meticulous dose calculation and use fixed doses of RAI (e.g., 185, 370, or 555 MBq). When evaluating the use of an ablative RAI dose in 576 GD patients 1 year after the first fixed RAI dose of 400 MBq, 17% were still hyperthyroid, 77% hypothyroid, and 6% euthyroid.[143] At 80-month follow-up, 81 patients had received a second dose, and eight patients a third dose; 3.2% were still hyperthyroid, 86.4% hypothyroid, 3.3% euthyroid, and 6.4% had died. Persistent thyrotoxicosis after the first RAI dose was associated with higher free T4 at diagnosis, higher pretreatment TSH-R–Ab, and post-RAI treatment with ATDs. New GO after RAI developed in 7.3%. RAI-associated GO is related to a steep increase in TSH-R–Abs; 3 years after RAI, TSH-R–Abs were still positive in 60% of patients.[85] Worsening or development of GO occurs more often after RAI than after treatment with ATDs (38% vs. 19%; relative risk, 1.94; 95% confidence interval: 1.4–2.7), as evident from two randomized clinical trials.[82] Hypothyroidism developed in 95% after RAI, but euthyroidism was not achieved by any participant.[82] One can conclude that elimination of Graves hyperthyroidism can be reached by RAI (although often a second, or sometimes a third, dose of RAI is required), but at the expense of a substantial risk of worsening or developing GO and creating a new disease—hypothyroidism.

Postoperative RAI for thyroid cancer increases the risk of second primary malignancies. as these doses are usually greater than 100 mCi.[144,145] Studies have been inconclusive for the risk of developing site-specific cancers after treatment with RAI for hyperthyroidism.[145,146] Doses of RAI are much less (10–15 mCi) for GD compared with postoperative cancer treatment, and absorption of radiation varies in different organs.[77] However, given the significant retained uptake within the thyroid gland in GD, the total body radiation exposure may actually be higher in treatment for GD versus cancer. A higher incidence of stomach, kidney, and breast cancers was reported in those who underwent RAI ablation for GD.[147] The multicenter Thyrotoxicosis Therapy Follow-up Study examined the radiation dose-response relationships for site-specific cancer death within the group of hyperthyroid patients (n = 18,805) who were treated with RAI.[145] This study did confirm an increased risk of secondary cancers (including breast) because of RAI treatment for hyperthyroidism. The average administered RAI activity was 10.1 mCi for GD. The relative risk of death from solid organ cancers (including breast) increases with greater doses of RAI. If patients are treated for hyperthyroidism at age 40 or 50 years, one in 31 to 52 patients or one in 32 to 55 would develop a secondary cancer. This long-term follow-up study may shift the decision-making process going forward about definitive treatment of GD.

In summary, there are no absolute indications for RAI therapy, but it is often recommended for patients with side effects from ATDs or recurrence after a course of ATDs. Verbal as well as written information regarding all aspects of efficacy and potential side effects of RAI therapy should be provided. If ATDs are used before RAI therapy, they should be paused around 1 week before and after therapy to avoid decreasing the efficacy of RAI therapy. No dose calculation can secure long-term euthyroidism, and it is fully acceptable to offer a fixed dose of RAI. Pregnancy and breastfeeding constitute to be absolute contraindications to RAI therapy. Conception should be postponed until at least 6 months after RAI in both males and females. If used in children, ablative doses aimed at rapid hypothyroidism should be administered.

THYROIDECTOMY

Advantages of total TX for hyperthyroidism allow for nearly 100% cure rates, identification of incidental cancers, and rapid achievement of euthyroid or hypothyroid states.[77,78] Total TX, when performed by a high-volume surgeon, is a cost-effective definitive treatment for GD,[148] with a failure rate of less than 1%.[77] Disadvantages of TX are perioperative and postoperative risks including bleeding, hypocalcemia, recurrent laryngeal nerve injuries, and the potential need for lifelong LT4 replacement. TX should be considered if there are compressive symptoms, suspicion for or known thyroid cancer, concurrent hyperparathyroidism, or large or substernal goiters, in pregnancy planning, pregnancy in the second trimester, or GD with nodular goiter and GO, if there is low RAI uptake, or if there is a need for fast, definitive therapy in thyrotoxicosis.[77,78,149] Preoperatively, patients should be on ATDs to establish a euthyroid state. Beta blockade is initiated for higher risk individuals, including elderly patients and those with severe thyrotoxicosis and cardiovascular disease.[42,136] In GD, inorganic iodide administration preoperatively decreases both blood flow to the thyroid and intraoperative blood loss, as well as improving the safety of TX, with decreased rates of transient hypoparathyroidism and hoarseness from transient recurrent laryngeal nerve injury.[150] The main risks of TX include anesthesia, bleeding, hypocalcemia with hypoparathyroidism, laryngeal edema, and recurrent laryngeal nerve injury. These risks, however, remain very low with experienced, high-volume surgeons (>100 thyroid surgeries per year).[151,152] Risks of recurrent laryngeal nerve injury and transient hypocalcemia are less than 1% and less than 10%, respectively.[153] In GD, preoperative vitamin D deficiency, female gender, and perioperative parathyroid autotransplantation are predictors for post-TX hypocalcemia.[154] Therefore, preoperative and postoperative supplementation with calcium carbonate and activated vitamin D, if needed, decrease rates of postoperative hypocalcemia.[155] Postoperatively, LT4 replacement is started on a weight-based calculation (1.4–1.6 μg/kg/day). TSH is measured by 6 to 8 weeks postoperatively to assess the dosing of LT4 replacement. Approximately 75% of patients will require subsequent dose adjustments before they are euthyroid.[156] In summary, if surgery is selected, total TX is the procedure of choice and should be performed by a skilled surgeon with high annual volumes of thyroidectomies. Euthyroidism should be restored by ATD before TX to avoid peri- or postoperative exacerbation of thyrotoxicosis. Vitamin D deficiency should be corrected to reduce the postoperative risk of hypocalcemia.

PERSPECTIVE AND CONCLUSION

A variety of new treatments are currently in clinical trials, which suggests that in the coming years we will have additional therapies in our armamentarium that hopefully avoid the disadvantages of our current approaches. Indeed, the novel and more disease-specific treatments for thyroidal GD aim to target primarily the TSH-R as the main autoantigen in GD and/or relevant for the pathogenesis of GD, as well as molecules playing an important role within the immunological synapse and expressed on the surface of B-cells (i.e., CD40 and CD20). In line with this, CD40 is abundantly expressed on the surface of thyrocytes and orbital target cells, and the CD40–CD154 interaction within the immunological synapse modulates humoral immunity.[157,158] Iscalimab (CFZ533), an anti-CD40 monoclonal antibody and a potent inhibitor of the CD40 pathway, led to an approximately 50% response rate when administered to patients with untreated Graves hyperthyroidism.[159]

However, in the future, causal treatment of GD will rely on monoclonal antibodies or small molecules inhibiting activation/hypertrophy of thyrocytes and orbital target cells. In detail, the disease-specific and most effective way to inhibit the increased release of free thyroid hormones induced by GD is to administer a TSH-R antagonist able to block the TSH-R and the stimulatory effect of the TSH-R–Abs. In this regard, a human anti-TSH-R monoclonal antibody (K1-70)[160,161] is being tested in a phase I trial in patients with GD. A significant concern is that this antibody has the potential for nontraditional signaling unrelated to TSH action. Further, a new, highly TSH-R–selective small molecule antagonist (S37a) was reported to inhibit TSH-R activation by both TSH itself and the human monoclonal stimulatory TSH-R–Ab M22.[162] Finally, the clinical effect of a combination of different TSH-R peptides called ATX-GD-59[163] able to stimulate the generation of regulatory T-cells and suppress the immune response against TSH-R was assessed in patients with untreated GD. A complete or partial short-term response was noted in 70%.[164]

EPIDEMIOLOGY

Graves' orbitopathy (GO), also known as thyroid eye disease, Graves ophthalmopathy, or thyroid-associated ophthalmopathy, is the most common extrathyroidal manifestation of Graves disease (GD). European Group on Graves' Orbitopathy (EUGOGO) estimated the prevalence of GO in Europe to be around 10 per 10,000 persons based on reported annual incidences of GO at approximately 5 per 100,000.[1] A recent meta-analysis involving 33 studies and over 20,000 patients suggested that the overall prevalence of GO in GD patients was 40%, and it did not significantly change with time when studies conducted before and after 2010 were compared.[2] Mild and moderate-to-severe GO accounted for around two-thirds and one-third of the cases, respectively, while 2% of GO patients suffered from sight-threatening GO.[1] Following the Amsterdam Declaration in 2009, which aimed at optimizing GO care, changes in referral patterns and epidemiology have been observed in European multidisciplinary GO centers. The increased proportion of patients with mild and inactive GO may be explained by several factors: (1) earlier referrals and assessments of GO in tertiary centres; (2) decline in the prevalence of smoking; (3) earlier diagnosis and treatment of Graves hyperthyroidism to maintain stable euthyroidism; and (4) more judicious (and probably less frequent) use of radioactive iodine (RAI) therapy in Graves hyperthyroidism.[3,4] Prompt multidisciplinary care is believed to improve both immediate and long-term outcomes of GO patients.

RISK FACTORS

Age

GO tends to affect middle-aged people, with an average age at diagnosis between 42 and 55 years.[3-5] Older age at onset of GO is associated with more severe disease presentation, including soft tissue involvement and ocular dysmotility, and predicts the development of dysthyroid optic neuropathy (DON), a form of sight-threatening GO.[6] A Danish study further showed that GD patients aged 40 to 60 years were at higher risk of developing moderate-to-severe GO compared with younger patients.[7]

Gender

Like Graves hyperthyroidism, GO is more common in women than in men. The overall female-to-male ratio was 3.7:1, according to large series from European and Australian tertiary referral centers.[3,4,6] It was shown previously that the ratio was inversely proportional to the severity of GO (mild 9.3:1; moderate 3.2:1; severe 1.4:1).[8] Recent DON cohorts revealed a female-to-male ratio of 2.8:1.[9-11] The association of male gender with more severe disease is well-recognized. Although the underlying pathophysiological mechanisms are not fully understood, the higher prevalence of smoking among men may at least partially explain the association.

Ethnicity

It has been suggested that certain ethnicities carry a higher risk of developing GO, but individual comparative studies showed conflicting results. A meta-analysis revealed a trend towards lower prevalence of GO among Caucasians (37%) compared with Asians (45%), but the difference was not statistically significant. The prevalence of GO stratified by continents/regions and ethnicities is shown in Fig. 72.1.[2]

Smoking

Cigarette smoking is associated with multiple negative effects on GO[12]: (1) the prevalence of smokers is higher in GD patients with GO compared with those without GO; (2) smokers suffer from more severe GO; (3) smoking renders immunomodulatory treatment of GO less effective; and (4) smoking increases the risk of progression or *de novo* development of GO after RAI. Smoking cessation may reduce the occurrence of proptosis and diplopia.

High Thyroid Stimulating Hormone Receptor Antibody Titer

In a multicenter prospective observational study, EUGOGO identified four independent predictors of GO development in patients with Graves hyperthyroidism, namely: current smoking, longer duration of hyperthyroid symptoms, clinical activity score (CAS) of at least 1, and high thyroidstimulating hormone receptor antibody (TSH-R–Ab) titer.[13] The relevance and utility of TSH-R–Ab in the management of GO will be discussed in the section "Thyroid Stimulating Hormone Receptor Antibody."

Radioactive Iodine Therapy

RAI is associated with a 4-fold increase in the risk of progression or *de novo* development of GO, affecting approximately 20% of those who receive RAI for Graves hyperthyroidism. The risk of post-RAI severe GO is around 7%.[14] Several factors further amplify the risk, including pre-existing GO, active smoking, high TSH-R–Ab titer, recent-onset hyperthyroidism, active or severe hyperthyroidism, and delayed correction of post-RAI hypothyroidism.[12,15] A recent Italian study suggested that patients with GD with a duration of more than 5 years were not at increased risk of exacerbation or *de novo* occurrence of GO. RAI results in a 4- to 5-fold increase in TSH-R–Ab titer, which peaks by 3 months post-treatment and then gradually returns to pre-treatment level by 1 year. This transient post-RAI deterioration in thyroid autoimmunity is believed to drive the progression or *de novo* development of GO.[16,17]

Cholesterol Level and Statin Use

In a cross-sectional study,[18] total cholesterol (TC) and LDL cholesterol (LDL-C) significantly correlated with the occurrence of GO in GD patients of relatively recent onset. TC above 191 mg/dL and LDL-C above 118.4 mg/dL were associated with a 47% and 28% increased risk of developing GO, respectively. A correlation was also found between CAS and TC/LDL-C levels. Another retrospective study confirmed the observation that TC/LDL-C levels were higher in GD patients with GO than those without GO.[19] Moreover, statin use for more than 60 days was associated with 40% decreased risk of GO in GD patients, whereas nonstatin cholesterol-lowering medications were not protective.[20] Future prospective trials will confirm whether statin use will impact on the occurrence and natural history of GO, as well as elucidate the mechanisms (e.g., cholesterol lowering, direct immunomodulatory actions) through which statin exerts its beneficial effects.[21]

KEY POINTS

- High thyroid stimulating hormone receptor antibody titer predicts the occurrence of Graves' orbitopathy. Smoking and radioactive iodine therapy are important modifiable risk factors. Older age and male gender are associated with more severe disease. Lower cholesterol levels and statin use are associated with lower risk of developing Graves' orbitopathy.

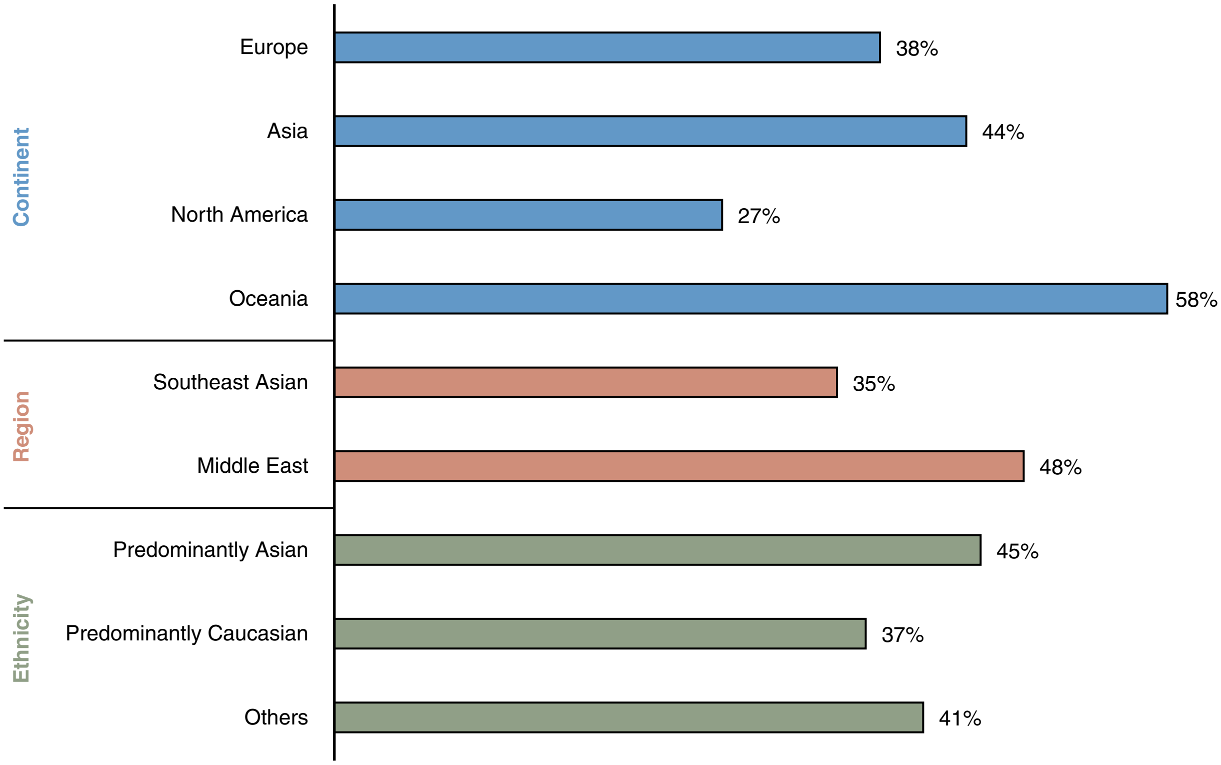

Fig. 72.1 Prevalence of Graves' orbitopathy in Patients with Graves Disease.

PATHOGENESIS

Key Pathological Changes in Graves' Orbitopathy

GO is characterized by three key pathological changes: (1) orbital inflammatory infiltration; (2) expansion of the adipose tissue within the connective tissue in extraocular muscles (sparing muscle fibers) and in other orbital adipose/connective tissues (i.e., *de novo* adipogenesis); and (3) increased production of hydrophilic glycosaminoglycans (GAG; mainly hyaluronan [HA]) by orbital fibroblasts (OFs), resulting in edema and further increase in the volume of various orbital tissues. These processes carry adverse mechanical consequences that explain most of the clinical manifestations of GO.

Thyroid Stimulating Hormone Receptor as the Putative Autoantigen

The close relationship between Graves hyperthyroidism and its associated orbitopathy suggests that thyroid stimulating hormone receptor (TSH-R) is the autoantigen shared by these two autoimmune disorders. Multiple immunohistochemical studies have confirmed the presence of TSH-R expression in orbital tissues (especially OFs and preadipocytes) of GO patients but not healthy individuals.[22] Similar TSH-R immunoreactivity was also demonstrated in pretibial fibroblasts from patients with Graves dermopathy, which is a less common extrathyroidal manifestation of GD.[23] The degree of TSH-R expression in GO orbital tissues correlated positively with serum TSH-R–Ab levels and negatively with disease duration.[22] In turn, serum TSH-R–Ab is a useful biomarker of disease activity and severity in GO (see "Thyroid Stimulating Hormone Antibody").

Immune Dysregulation

Pattern of Orbital Inflammatory Infiltration. The mononuclear cell infiltrates comprise predominantly T-cells (especially CD4+, also CD8+/CD45RO+ and CD45RB+) and monocytes/macrophages, consistent with the notion that GO is primarily a T-cell–mediated disease. Infiltration of mast cells and dendritic cells has been occasionally reported. In contrast, B-cells were much less prominent or even absent in certain immunohistochemical studies.[22] The magnitude of inflammatory infiltration correlated with the disease status.[22] The early or active phase of GO (when compared with the late or inactive phase) was associated with more prominent cellular infiltration by T-cells (especially CD4+), monocytes/macrophages, and major histocompatibility complex (MHC) class II+ cells (human leukocyte antigen [HLA]-DR, -DP, -DQ, or -DX). Severe GO (when compared with mild GO) was associated with more prominent T-cell infiltration, whereas CAS was positively correlated with the degree of lymphocyte or macrophage infiltration.

Interaction of T- and B-Cells in Graves' Orbitopathy. The exact mechanisms causing disruption of immune tolerance to self antigens (especially TSH-R) in GO are yet to be elucidated. Antigen-presenting cells (e.g., B-cells, monocytes/macrophages, dendritic cells) recognize and present TSH-R peptides through MHC class II molecules to T-cell receptors of autoreactive T helper (Th) cells. Upregulation of HLA-DR (a MHC class II molecule) expression was evident in GO orbital tissues compared with healthy controls.[22] Antigen recognition constitutes the first signal for T- or B-cell activation, and the second signal by costimulation is required for their full activation. The binding of CD40 ligand (CD40L or CD154) on the T-cell surface to CD40 on the B-cell surface activates B-cells. The CD40–CD40L interaction is followed by CD28 expression on the T-cell surface and B7 expression on the B-cell surface, and the B7–CD28 interaction leads to full activation of T-cells. The CD40–CD40L costimulatory pathway is essential for T-cell activation and the T-cell–dependent humoral immune response, playing an important role in activation of autoreactive B-cells and subsequent production of pathogenic TSH-R–Ab by plasma cells. The observations that rituximab resulted in both B- and T-cell depletion on orbital tissue immunohistochemistry and that the efficacy of rituximab in GO was not consistently associated with a decline in serum TSH-R–Ab level suggest that B-cell–T-cell interaction and antigen presentation are important components during the early phase of the pathogenesis.[22,24] This is in keeping with the impression from clinical trials that patients with GO of recent onset (instead of those with longer disease duration) benefited from rituximab therapy.[25]

Roles of B- and T-Cells in Graves' Orbitopathy. The principal role of B-cells in GO is believed to be antigen presentation to Th cells, which leads to activation of both types of lymphocytes through costimulation, resulting in production of autoantibodies and various proinflammatory cytokines as well as adhesion molecules. These stimuli not only amplify and maintain orbital inflammation, but also promote activation, proliferation, and differentiation of OFs. The consequences are GAG deposition and tissue edema, *de novo* adipogenesis, orbital tissue remodeling, and ultimately fibrosis.

CD4+ T-cells, which dominate orbital inflammatory infiltration, are classified into the following subtypes: Th1, Th2, Th17, and regulatory T (Treg) cells. Th1 cells mediate the cell-mediated immune response and produce interleukin (IL)-1β, IL-2, interferon (IFN)-γ, and tumor necrosis factor (TNF)-α. These proinflammatory cytokines result in OF activation and proliferation, as well as enhanced GAG production. Th2 cells, with a cytokine profile comprising IL-4, IL-5, IL-10, and IL-13, mediate humoral immunity and autoantibody production, as well as tissue remodeling and fibrosis. It is postulated that Th1 immunity is important in initiating GO development during the early stage of the disease, whereas Th2 immunity is responsible for the chronic phase of GO.[23 26]

Th17 is a recently identified CD4+ T-cell subset that is implicated in the pathogenesis of GO owing to its proinflammatory and profibrotic properties. Recent evidence suggests that there is a close interplay between Th17 cells and OFs.[26] IL-17A, the signature cytokine of Th17 cells, promoted the secretion of proinflammatory cytokines (IL-6, IL-8, monocyte chemotactic factor-1, regulated on activation normal T-cell expressed and secreted [RANTES], TNF-α, granulocyte macrophage colony stimulating factor), costimulatory molecules (CD40, MHC class II), and adhesion molecules (vascular cell adhesion molecule-1 [i.e., CD106], intracellular adhesion molecule-1 [ICAM-1, i.e., CD54]) by OF. IL-17A also enhanced profibrotic functions of OFs, including extracellular matrix deposition, transforming growth factor-β (TGF-β)-induced differentiation into myofibroblasts, and subsequent fibrosis. OFs in turn triggered Th17 differentiation and supported Th17 functions via prostaglandin E2 (PGE2). In contrast, IL-17A suppressed adipogenesis. Th17 cells also promoted proinflammatory and antigen-presenting functions of GO fibrocytes, which enhanced Th17 cell function and recruitment.[26]

Treg cells are important in controlling autoimmunity, and higher levels in peripheral circulation are associated with favorable treatment response and clinical improvement in GO. The importance of T-cell immunity has been reproduced in a recent mouse model of GO.[27] When administered an adenovirus expressing the human TSH-R A subunit, seven of 10 mice developed orbital changes associated with GO. Increased proportions of Th1 cells and decreased proportions of Th2/Treg cells in the splenocytes of GO mice, as detected by flow cytometry, were accompanied by the same change in CD4+ T-cell subgroups as detected by orbital immunohistochemical staining. Furthermore, there was an upregulation of genes involved in T-cell receptor signaling, proliferation, adhesion, inflammation, and cytotoxicity in GO mice.

Orbital Fibroblasts as Key Effector Cells in Graves' Orbitopathy

OFs mediate most of the pathological changes in GO under the influence of various stimuli, including cytokines, growth factors, CD40–CD40L interaction, and TSH-R–insulin-like growth factor-1 receptor (IGF-1R) crosstalk.[23] IFN-γ and IL-1β stimulate OFs to produce proinflammatory cytokines and chemoattractants (e.g., C-X-C motif ligand-9 (CXCL-9), CXCL-10, CXCL-11, C-C motif ligand-2 (CCL2), CCL5, IL-6, IL-8, IL-16, RANTES), leading to migration and infiltration of lymphocytes, monocytes, and neutrophils. The interaction between CD40L on T-cells and CD40 on OFs results in activation and proliferation of OFs, as well as the release of inflammatory molecules (e.g., IL-1α, IL-6, IL-8, CCL2, PGE2). PGE2 potentiates B-cell maturation, stimulates IL-6 synthesis by OFs and activates mast cells. Other cytokines (e.g., leukoregulin, IL-1β from macrophages or OFs, IFN-γ from activated T-cells) can also stimulate OFs to produce PGE2. B-cell activating factor (BAFF) plays an important role in promoting B-cell survival and maturation, as well as inducing immunoglobulin class-switching recombination. TNFα and IFN-γ enhance BAFF expression by OFs. IL-1α, IL-1β, TNF-α, IFN-γ, and CD40–CD40L interaction enhance expression of ICAM-1 on OFs, which augments T-cell recruitment during the active phase of the disease.

Platelet-derived growth factors (PDGFs) were found to be overexpressed by monocytes, macrophages, and mast cells (but not T- or B-cells) in orbital tissues of GO patients.[22] Different PDGF isoforms were capable of stimulating proliferation, HA and cytokine/chemokine (e.g., IL-6, IL-8, IL-16, RANTES, CCL2, CCL5, CCL7) production, and TSH-R expression by OFs. Of these PDGF isoforms, PDGF-BB exhibits the strongest OF-activating effects, which is likely related to its ability to bind both α and β chains of the PDGF receptor.[28]

The overproduction of hydrophilic HA by OFs was stimulated by TSH-R/IGF-1R activation (discussed in more detail below) and various inflammatory mediators, such as IL-1, TNF-α, IFN-γ, TGF-β, IGF-1, PDGF, and prostaglandins, through upregulation of HA synthases (the major isoform being HA synthase-2 [HAS2]). *In vitro* studies reported undetectable hyaluronidase activity in GO OFs. The imbalance between overproduction and impaired degradation probably explains the HA accumulation in OG orbital tissues.[8,23]

OFs can be classified into Thy1- (CD90-) and Thy1+ subpopulations based on the presence or absence of CD90 glycoprotein expression.[23] Thy1- OFs (preadipocytes) possess a strong capability to differentiate into mature adipocytes. Peroxisome proliferator-activated receptor-γ (PPARγ) is highly expressed in Thy1- OFs. PPARγ agonists (e.g., rosiglitazone) enhanced adipogenesis and expression of TSH-R in Thy1- OFs. In contrast, they inhibited orbital inflammation and GAG production. IL-1β, IL-6, and proadipogenic prostaglandins (PPARγ ligands) also stimulated Thy1- OFs to undergo adipogenesis, while certain Th1 cytokines (e.g., TNFα, IFNγ) inhibited the process. On the other hand, Thy1+ OFs are able to differentiate into myofibroblasts under stimulation by TGF-β (a type of Th2 cytokine). Myofibroblasts play an essential role in mediating deposition of extracellular matrix (e.g., collagen) and eventually tissue fibrosis. It was shown that Thy1+ OFs suppressed adipocytic differentiation of Thy1- OFs by producing antiadipocytic factors. Therefore, the balance and relative proportion of Thy1- and Thy1+ OFs modulate the presentation of tissue remodeling in GO.

Signaling Pathways Mediating Hyaluronan Production and Adipogenesis (Fig. 72.2)

TSH-R activation of GO OFs switched on G protein Gαs, which triggered adenylate cyclase activation and generation of cyclic adenosine monophosphate (cAMP), leading to activation of cAMP dependent protein kinase A (PKA). Direct phosphorylation of cAMP-response element binding protein (CREB), a transcription factor, was catalyzed by activated PKA. CREB then bound to the HAS1 and HAS2 promoters, leading to increased HA production. On the other hand, stimulation of IGF-1R activated phosphatidylinositol 3-kinase 1A (PI3K1A)-Akt/PKB-mammalian target of rapamycin complex 1 (mTORC1) pathway.[29] PI3K signaling specifically regulated HA production via HAS2, while mTORC1 was essential for adipogenesis.[30] Forkhead transcription factors, forkhead box O (FOXO) subtypes, were tightly regulated via Akt within the PI3K signaling cascade. Enhancing FOXO3a expression significantly decreased HAS2/HA production in GO OFs, whereas FOXO1 repressed adipogenesis. FOXOs were also able to counteract TSH-R–activated HAS2/HA production and block adipogenesis in GO OFs.[31] Enhanced TSH-R expression, which accompanied adipocytic differentiation, may thus be indirectly attenuated through inhibition of the PI3K/mTORC1 pathway. Therefore, FOXOs probably serve as convergence points for TSH-R and IGF-1R signaling pathways in GO.[29]

Orbital Infiltration of CD34+ Fibrocytes

Fibrocytes are CD34+ bone marrow–derived progenitor cells of the monocyte lineage. They normally circulate at low concentrations but become more abundant in GD patients. It is postulated that they infiltrate the orbits and initiate the development of GO. Fibrocytes present thyroid antigens (e.g., TSH-R, thyroglobulin, thyroperoxidase, sodium-iodide symporter) to antigen-specific autoreactive T-cells, which in turn activate B-cells and subsequent autoantibody generation. Fibrocytes differentiate into CD34+ OFs, which can further differentiate into myofibroblasts and adipocytes. Although only CD34- OFs are present in normal orbits, a mixture of CD34+ OFs (~50% of the whole population of OF) and the residential CD34- OFs coexist in GO orbits. Both fibrocytes and GO OFs express high levels of TSH-R/IGF1-R and produce various inflammatory molecules (e.g., proinflammatory cytokines, adhesion molecules, growth factors, etc.), leading to mononuclear cell infiltration. The importance of TSH-R/IGF-1R will be discussed below. Bidirectional stimulation between lymphocytes and GO OFs results in perpetuation of orbital inflammation and tissue remodeling. Interestingly, recent studies suggested that Slit2, a glycoprotein produced by residential CD34- OFs, appeared to downregulate the inflammatory phenotype of CD34+ OFs, and thus potentially attenuate the manifestations of GO.[32-34]

Thyroid Stimulating Hormone Receptor and Insulin-Like Growth Factor-1 Receptor Crosstalk (Fig. 72.3)

Multiple immunohistochemical studies have confirmed the presence of TSH-R expression in orbital tissues of GO patients but not in healthy individuals,[22] suggesting that TSH-R is one of the primary autoantigens in GO. Activation of TSH-R stimulated production of proinflammatory cytokines (e.g., IL-6, TNF-α) and GAG by GO OFs/fibrocytes. There was a positive correlation between TSH-R mRNA levels in GO orbital tissues and disease activity.[33,35]

IGF-1R was overexpressed in GO OFs and lymphocytes. Accumulating evidence suggests that IGF-1R forms a physical and functional complex with TSH-R and that its activity is important for mediating TSH-R downstream signaling[36,37]:

1. TSH-R and IGF-1R were in close proximity in a signalosome, in which β-arrestin 1 acted as a scaffold.
2. Simultaneous activation of TSH-R and IGF-1R (by TSH and IGF-1, respectively) synergistically increased HA secretion by GO OFs.
3. IGF-1–induced HA secretion was effectively inhibited by linsitinib (IGF-1R kinase inhibitor) or IGF-1R blocking antibodies (AF305 and 1H7). However, only linsitinib and 1H7 (but not AF305) suppressed

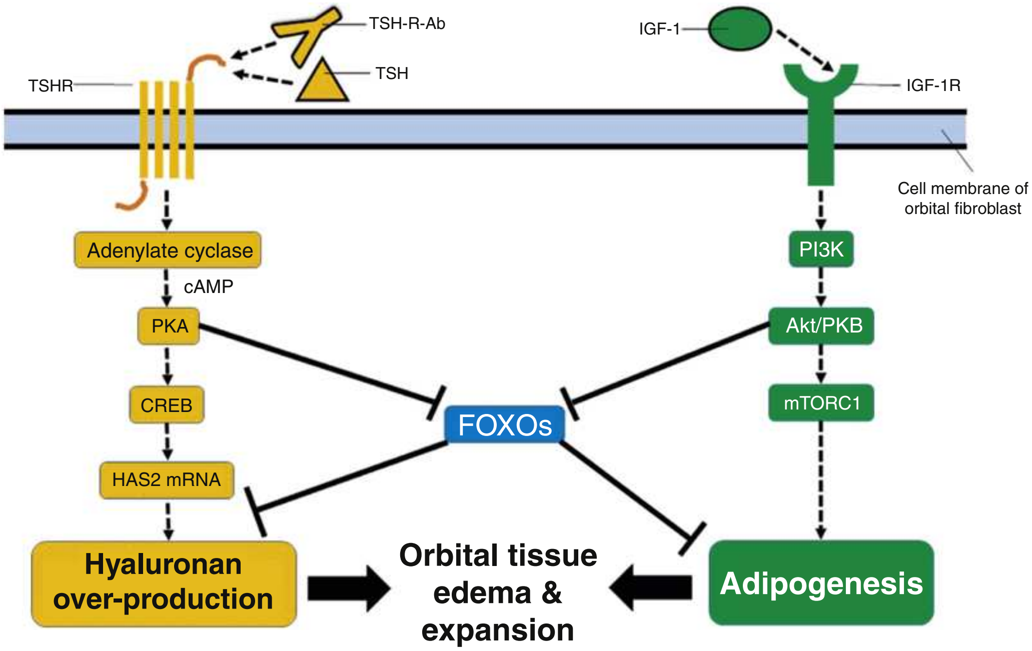

Fig. 72.2 Signaling Pathways of Thyroid-Stimulating Hormone Receptor (TSH-R) and Insulin-Like Growth Factor-1 Receptor (IGF-1R) in Graves' Orbitopathy. TSH-R and IGF-1R activation directly stimulate hyaluronan production and adipogenesis in orbital fibroblasts, respectively. Both pathways can also activate orbital fibroblasts through suppressing expression of FOXOs, which potentially serve as the convergence point of TSH-R/IGF-1R signaling pathways. *Akt/PKB*, Protein kinase B; *cAMP*, cyclic adenosine monophosphate; *CREB*, cAMP response element–binding protein; *FOXOs*, forkhead box O family of transcription factors; *HAS2*, hyaluronan synthase-2; *IGF-1*, insulin-like growth factor-1; *IGF-1R*, insulin-like growth factor-1 receptor; *mTORC1*, mammalian target of rapamycin complex 1; *PI3K*, phosphatidylinositol 3-kinase; *PKA*, protein kinase A; *TSH*, thyroidstimulating hormone; *TSH-R–Ab*, thyroidstimulating hormone receptor antibody.

Fig. 72.3 Thyroidstimulating Hormone Receptor (TSH-R)/Insulin-Like Growth Factor-1 Receptor (IGF-1R) Crosstalk. TSH-R and IGF-1R are in close proximity within a signalosome, with β-arrestin 1 acting as a scaffold. TSH-R stimulation activates two signal transduction pathways, one being IGF-1R-independent *(orange arrow)* and the other IGF-1R-dependent *(blue arrow)*. Therefore, both TSH-R and IGF-1R pathways combine through crosstalk, resulting in more potent stimulation of hyaluronan production. *IGF-1*, Insulin-like growth factor-1; *IGF-1R*, insulin-like growth factor-1 receptor; *TSH*, thyroidstimulating hormone; *TSH-R–Ab*, thyroidstimulating hormone receptor antibody.

HA secretion by GO OFs induced by M22 (TSH-R stimulatory monoclonal antibody) or immunoglobulins from GO patients (GO-Ig).

4. TSH-R antagonist (ANTAG3) completely suppressed M22-induced HA secretion by GO OFs, regardless of M22 concentration. In contrast, linsitinib and 1H7 fully antagonized HA secretion induced by M22 at low concentration, but their efficacy diminished at high concentration of M22. Individually, ANTAG3, linsitinib, and 1H7 (all at half maximally effective inhibitory concentrations) incompletely inhibited GO-Ig–induced HA secretion, while the combination of ANTAG3 and linsitinib/1H7 additively suppressed HA secretion.

In summary, the stimulation of TSH-R activates two signal transduction pathways, one being IGF-1R–independent and the other IGF-1R–dependent (i.e., TSH-R/IGF-1R crosstalk pathway). TSH-R– and IGF-1R–mediated pathways cooperate through crosstalk, resulting in more intense activation of OFs. IGF-1R autoantibodies were present in both normal individuals and GD patients with or without GO. Although GO-Ig was able to displace IGF-1 from the binding sites of IGF-1R on the surface of GO OFs, the current consensus is that stimulatory IGF-1R autoantibodies are not directly involved in the pathogenesis of GO[38]

Genetic Susceptibility

The etiology of GD has a strong genetic component, as evidenced by greater concordance rate among identical twins compared with nonidentical twins and high sibling risk ratios among family members of GD patients. Several genetic loci have been shown to be associated with GD susceptibility, including *HLA* genes (e.g., HLA*DR3 and DQA*10501 haplotypes in Caucasians), immune-related genes (e.g., *CTLA-4, CD25, CD40, PTPN22, FOXP3*), and thyroid-specific genes encoding thyroglobulin and TSH-R.[39] In recent years, multiple genetic polymorphisms have also been reported to be associated with GO, involving *CTLA-4* (SNP49 polymorphism),[40] adipocyte-related immediate early genes (IEGs), and immunomodulatory genes (cysteine-rich, angiogenic inducer 61, zinc finger protein 36, C3H type, homolog mouse, and stearoyl-coenzyme A desaturase),[41] interleukin-1A (rs1800587, c.-889C>T),[42] *TSH-R* (rs179247 and rs12885526),[43] FC receptor-like-3 (FCRL3_3C, FCRL3_5C, FCRL3_6A),[44],methylenetetrahydrofolate reductase gene (TT genotype),[45] tumor necrosis factor super family-15 ((rs3810936 and rs4979462 polymorphisms),[46] and *HLA* genes.[47]

Fig. 72.4 summarizes the key components involved in the pathogenesis of GO.

KEY POINTS

- Thyroidstimulating hormone receptor (TSH-R) is believed to be the primary autoantigen in Graves' orbitopathy (GO). The loss of immune tolerance leads to orbital inflammatory infiltration and activation of orbital fibroblasts, resulting in perpetuation of inflammation, excessive glycosaminoglycan production and subsequent tissue edema, *de novo* adipogenesis, and ultimately tissue remodeling and fibrosis. TSH-R–insulin-like growth factor-1 receptor crosstalk and their signaling pathways are central to the pathophysiology of GO.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

GO can present with a wide spectrum of clinical features, from non-specific to pathognomonic symptoms and signs, and from trivial complaints to disabling and sight-threatening complications (Table 72.1).

The diagnosis of GO is usually established clinically based on compatible clinical features, while thyroid function test, TSH-R–Ab assessment, and orbital imaging will provide further supportive evidence. As GO has significant impact on patients' quality of life (QoL), QoL assessment forms an integral part in the evaluation of GO.

Clinical Evaluation

EUGOGO recommends the assessment of both activity and severity of GO according to standardized criteria, and subsequent classification as inactive or active, and mild, moderate-to-severe, or sight-threatening.[12] Accurate assessment is essential in determining the most appropriate treatment strategies for GO patients. CAS is the most well-established tool used to assess disease activity in both daily practice and clinical trial settings (Table 72.2). A CAS value of 3/7 or more or 4/10 or more indicates active GO, which necessitates immunomodulatory treatment. Disease severity is determined by five components: soft tissue involvement as reflected by 7-point CAS value (excluding pain parameters), upper lid retraction, diplopia, proptosis, and evidence of sight-threatening complications (Table 72.3).

Asymmetrical and Unilateral Graves' Orbitopathy. GO is considered a generalized orbital disease. Asymmetrical or unilateral involvement can occur, although there is no established definition of this clinical entity. In a recent prospective cross-sectional multicenter study involving new referrals to EUGOGO centers,[48] unilateral GO was defined as one or more clinical features of GO in one eye only. Asymmetrical GO was defined as bilateral disease with one or more of the following features: (1) difference in exophthalmometer readings of 2 mm or more; (2) difference in palpebral aperture of 2 mm or more; (3) difference in eyelid swelling by one grade or more; (4) difference in eyelid erythema by one grade or more; (5) difference in conjunctival redness by

Fig. 72.4 **Pathogenesis of Graves' Orbitopathy (GO)—an Overview. TSH-R is Believed to be the Primary Autoantigen in GO.** The loss of immune tolerance generates autoreactive T- and B-cells, which are activated by costimulation and cytokines. Orbital fibroblasts becomes activated by various stimuli (cytokines/growth factors, TSH-R/IGF-1R signaling and crosstalk after stimulation by TSH-R–Ab, and CD40–CD40 ligand interaction with T-cells). Orbital fibroblasts play a central role in mediating the key pathological changes in GO, including orbital inflammatory infiltration, *de novo* adipogenesis, hyaluronan overproduction, with resultant tissue edema, expansion, remodeling, and fibrosis. *IGF-1R*, Insulin-like growth factor-1 receptor; *MHC*, major histocompatibility complex; *TSHR*, thyroid-stimulating hormone receptor; *TSH-R–Ab*, thyroidstimulating hormone receptor antibody; *GAG*, glycosaminoglycan.

TABLE 72.1 Clinical Features of Graves' Orbitopathy

Clinical Features	Pathophysiology and Clinical Significance
• Gritty or foreign body sensation, light sensitivity (photophobia), excess tearing	• Ocular surface irritation resulting from increased evaporative loss and/or impaired tear film formation because of proptosis or eyelid abnormalities • May mimic other common ocular conditions, e.g., allergic conjunctivitis, dry eye disease
• Eyelid swelling and redness • Conjunctival swelling (chemosis) and redness • Caruncle or plica swelling • Gaze-evoked pain or spontaneous retrobulbar pain • Elevated intraocular pressure	• Reflect orbital inflammation and congestion
• Upper eyelid retraction	• Sympathetic activation of Muller's muscle • Synkinetic activity of levator palpebrae superioris with superior rectus that tries to overcome the tight inferior rectus • Inflammation, degeneration, and scarring of eyelid structures
• Lower eyelid retraction/displacement	• Correlates with the degree of proptosis • Lower lid retractors apparently unaffected in Graves' orbitopathy
• Lid lag	• Defined as a static phenomenon in which the upper eyelid assumes and maintains a higher position (relative to its position in primary gaze) with the eye in downgaze
• Von Graefe's sign	• Defined as a dynamic phenomenon in which the upper eyelid fails to descend smoothly and lags behind the eyeball during the course of downgaze
• Lagophthalmos	• Incomplete eyelid closure because of eyelid abnormalities and significant proptosis • Predisposes to exposure keratopathy, especially when Bell's phenomenon is defective owing to tight inferior rectus
• Diplopia and squint	• The proliferation of orbital fibroblasts (*de novo* adipogenesis, secretion and accumulation of hydrophilic glycosaminoglycans) and inflammatory infiltration lead to enlargement of extraocular muscles, resulting in restrictive (instead of paralytic) strabismus
• Proptosis	• Expanded volume of retrobulbar structures pushes the eyeball forward • Globe subluxation may occur in extreme proptosis
• Visual loss	• Watch out for sight-threatening Graves' orbitopathy

TABLE 72.2 Clinical Activity Score

Parameters	7-Point CAS	10-Point CAS
1. Spontaneous retrobulbar pain 2. Pain on attempted upward/downward/side gaze 3. Redness of eyelids 4. Redness of conjunctiva 5. Swelling of eyelids 6. Swelling of conjunctiva (chemosis) 7. Swelling of caruncle or plica 8. Increase of ≥2 mm in proptosis 9. Decrease in uniocular excursion in any one direction of ≥8 degrees 10. Decrease in visual acuity equivalent to 1 Snellen line	• Applicable to first clinical assessment or during subsequent follow-ups (parameters 1-7)	• Applicable during subsequent follow-ups (parameters 1-10)

CAS, Clinical activity score.

- One point is given to each of the seven signs and symptoms in the 7-point CAS during initial assessment.
- On subsequent follow-up, either the 7-point or the 10-point CAS (which includes three additional parameters, namely deterioration in ocular dysmotility, proptosis, or visual acuity) can be used.

one grade or more; (6) presence of unilateral DON. Some 58% of GO patients had symmetrical disease, whereas 31% and 11% had asymmetrical and unilateral disease, respectively. Compared with the symmetrical and unilateral groups, the asymmetrical group had an older mean age, lower female-to-male ratio, and more active and severe disease. Whereas asymmetry is a potential indicator of more active and severe GO than other clinical variants, unilaterality is associated with less severe disease.

Dysthyroid Optic Neuropathy. DON is the most common form of sight-threatening GO. Direct compression of swollen extraocular muscles on the optic nerve at orbital apex is believed to be the pathogenic mechanism in over 90% of cases. However, some propose that optic nerve stretch in the presence of marked proptosis may explain a minority of cases, although this theory remains controversial. The most common symptom is visual blurring. Approximately 50% of affected patients have bilateral, but not necessarily symmetrical, involvement (simultaneous or sequential). Although there are no established diagnostic criteria validated for DON, the salient diagnostic features are summarized in Table 72.4.

Thyroid Function Test

Over 95% of GO cases are associated with Graves hyperthyroidism.[49,50] Although GO most commonly occurs simultaneously with or after the onset of hyperthyroidism, it precedes the onset of hyperthyroidism in 20% of patients (and most of them are diagnosed within

TABLE 72.3 Assessing Severity of Graves' Orbitopathy

	Mild Graves' Orbitopathy	Moderate-to-Severe Graves' Orbitopathy	Sight-Threatening Graves' Orbitopathy
General description	• Minimal impact on daily life • Usually present ≥1 of the following signs:	• No sight-threatening GO • Significant impact of daily life to justify the risks of immunosuppressants (if active) or surgical intervention (if inactive) • Usually present ≥2 of the following signs:	• Presence of any one of the following features: • Dysthyroid optic neuropathy • Corneal breakdown because of severe exposure • Globe subluxation • Choroidal folds • Postural visual darkening
Soft tissue involvement	Mild	Moderate or severe	
Lid retraction	<2 mm	≥2 mm	
Proptosis	<3 mm above normal for race and gender	≥3 mm above normal for race and gender	
Diplopia	Absent or intermittent	Inconstant or constant	
Corneal exposure	Responsive to lubricants		

TABLE 72.4 Diagnosis of Dysthyroid Optic Neuropathy

Clinical Features	Examples of Diagnostic Test	Frequency in Dysthyroid Optic Neuropathy	Remarks
1. Reduced BCVA	Snellen chart	• 82%	• No single BCVA threshold can exclude DON, and 20% of cases have BCVA >0.67
2. Reduced color vision	Ishihara test	• 83%	• One of the most specific features • Can be present even if BCVA appears normal
3. RAPD	Swinging flashlight test	• 44%	• Possible only in unilateral DON or bilateral DON with significant asymmetry
4. Papilloedema	Fundoscopy	• 40%	• One of the most specific features • Optic disc pallor (present only in ~4%) may be observed in longstanding severe optic nerve dysfunction
5. Visual field defect	Automated perimetry	• 64%	• Most common patterns include central scotoma, an arcuate or altitudinal defect
6. Abnormal electrophysiology	Visual-evoked potentials	• 73% (↑ latency) • 53% (↓ amplitude)	• Helpful to exclude DON if unequivocally normal • Interference by thyroid dysfunction and lack of reference range in elderly may make interpretation difficult • Time-consuming and not widely available
7. Apical crowding on imaging	CT or MRI orbits	• 95%	• Apical crowding is quantified by assessing the degree of perineural fat effacement on coronal images at the orbital apex • Less commonly imaging shows no apical crowding but reveals optic nerve stretching ± tenting at posterior eyeball because of severe proptosis

BCVA, Best corrected visual acuity; *CT*, computed tomography; *DON*, dysthyroid optic neuropathy; *MRI*, magnetic resonance imaging; *RAPD*, relative afferent pupillary defect.

- Expert opinion suggests that DON can be diagnosed if papilloedema (after excluding alternative causes) is present or if two of the following features are present: impaired visual acuity or color vision, RAPD, and visual field defect.
- A US group developed a mathematical formula, the Columbia thyroid eye disease-compressive optic neuropathy diagnostic formula (CTD formula), which helps guide clinicians in accurately diagnosing DON. The parameters include visual acuity, color vision, RAPD, visual field defect, ocular dysmotility, and proptosis. However, this has not been prospectively validated.

6 months before the diagnosis of hyperthyroidism).[51] Approximately 5% of GO cases are associated with primary hypothyroidism because of Hashimoto thyroiditis ("hypothyroid GO," i.e., hypothyroidism diagnosed before or within 6 months after GO onset) or euthyroidism ("euthyroid GO," i.e., euthyroid before and within 6–24 months after GO onset).[49,50] Two German cohorts reported that hypothyroid or euthyroid GO was different from hyperthyroid GO in several ways:[49,52] (1) less active and milder disease; (2) more likely to be unilateral or asymmetrical; (3) lower levels of TSH-R–Ab and higher prevalence of negative thyroid autoantibodies; (4) less likely to require intravenous glucocorticoids (GCs) or orbital radiotherapy; and (5) less sick leave or work disability observed and better QoL.

Thyroid Stimulating Hormone Receptor Antibody

TSH-R–Ab refers to any type of autoantibody that interacts specifically with TSH-R. There are three functional subtypes of TSH-R–Ab: (1) TSH-R–stimulating antibody (TSAb), which stimulates unregulated thyroid growth and thyroid hormone production; (2) TSH-R–blocking antibody (TBAb), which blocks the activity of the natural ligand TSH to TSH-R; and (3) neutral TSH-R–Ab, which carries uncertain clinical significance. Serum TSH-R–Ab level is commonly quantified by competitive binding immunoassays (TSH-R–binding inhibitory immunoglobulin, TBII), which do not differentiate the functionality of different subtypes. On the other hand, cell-based bioassays measure specifically the activity of TSAb and TBAb.[35,53]

TSH-R–Ab (especially TSAb) measurement complements clinical and radiological assessment of GO, adding another dimension to diagnosis, disease monitoring, and prediction of clinical course, as well as the risk of developing GO. TSAb is more sensitive and specific than TBII in GO,[54] and overall TSH-R–Ab is a useful marker to differentiate GO from other orbital diseases.[55] TSH-R–Ab levels correlated positively with the activity and severity of GO and negatively with the duration of GO. The association of TSAb with clinical features of GO was much stronger than TBII.[54,56-58] TSAb was also associated with DON of recent onset, and it may help identify patients who require urgent treatment.[59] A recent study measured TSH-R–Ab levels (by immunoassays and cell-based bioassay) in patients with thyroidal GD only and GD plus GO.[60] The baseline undiluted samples from the two groups revealed an overlap in the ranges of TSH-R–Ab levels. However, serial dilution analyses showed that, in both hyperthyroid and euthyroid states (after methimazole), GD plus GO samples remained positive for TSH-R–Ab at high dilutions, while GD samples turned negative at low dilutions. Therefore, high TSH-R–Ab titer revealed by dilution analyses may serve as a useful parameter to predict the risk of GD patients developing GO.

Orbital Imaging

The diagnosis of GO can be established in most cases by clinical evaluation and blood tests (thyroid function test, TSH-R–Ab assessment) alone. However, orbital imaging should be considered in the following scenarios: (1) atypical presentation (e.g., euthyroid, absence of thyroid autoantibodies, unilateral or grossly asymmetrical disease)—alternative orbital diseases have to be excluded; (2) suspected DON—imaging may show apical crowding, frank optic nerve compression, or, less commonly, optic nerve stretch; (3) operative planning before orbital decompression or eye muscle surgery; and (4) inconclusive clinical evaluation (e.g., CAS, severity parameters)—imaging can provide more objective evidence of disease status and aid future monitoring.

Expansion of orbital tissues is characteristic of GO. Expansion of fat component because of *de novo* adipogenesis is the main contributor to proptosis (Fig. 72.5). Extraocular muscle enlargement most often involves the inferior rectus, followed by the medial, superior, and lateral rectus. Multiple muscles are involved in most cases (Fig. 72.6A and B). Enlarged muscle belly with sparing of the tendinous insertion is typical but not pathognomonic, as up to 6% of GO patients may show thickening of extraocular muscle tendon, and non-GO ocular myositis can present without tendon involvement. The degree of apical crowding secondary to extraocular muscle enlargement, which can be semiquantified on imaging, correlates with the risk of DON (Fig. 72.6A and B). Expanded orbital volume and venous congestion can result in dilated superior ophthalmic vein, anterior displacement of the lacrimal gland, intracranial fat prolapse through the superior orbital fissure, and bone remodeling (e.g., bowing of the lamina papyracea because of enlarged medial rectus muscle). The lacrimal gland itself can become enlarged because of venous congestion and/or inflammatory infiltration.

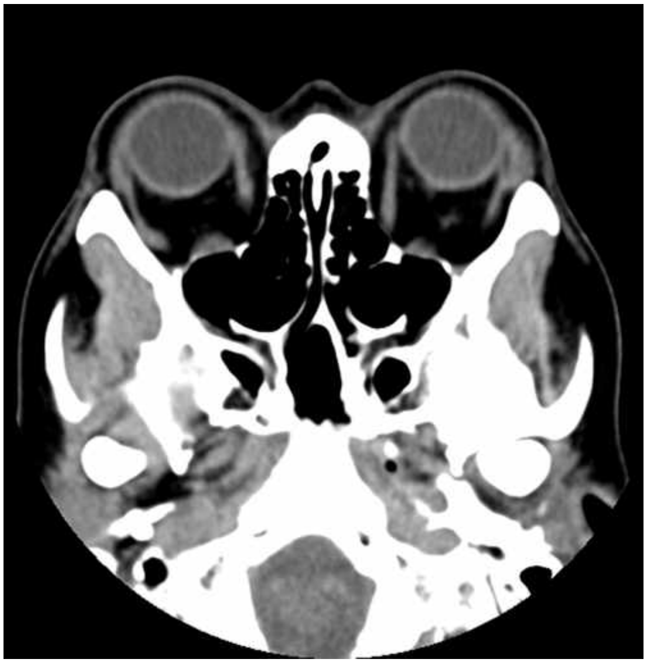

Fig. 72.5 Axial Orbital Computed Tomograpy Image of a 52-Year-Old with Inactive Graves' Orbitopathy, Showing Bilateral Proptosis and Expanded Retrobulbar Fat.

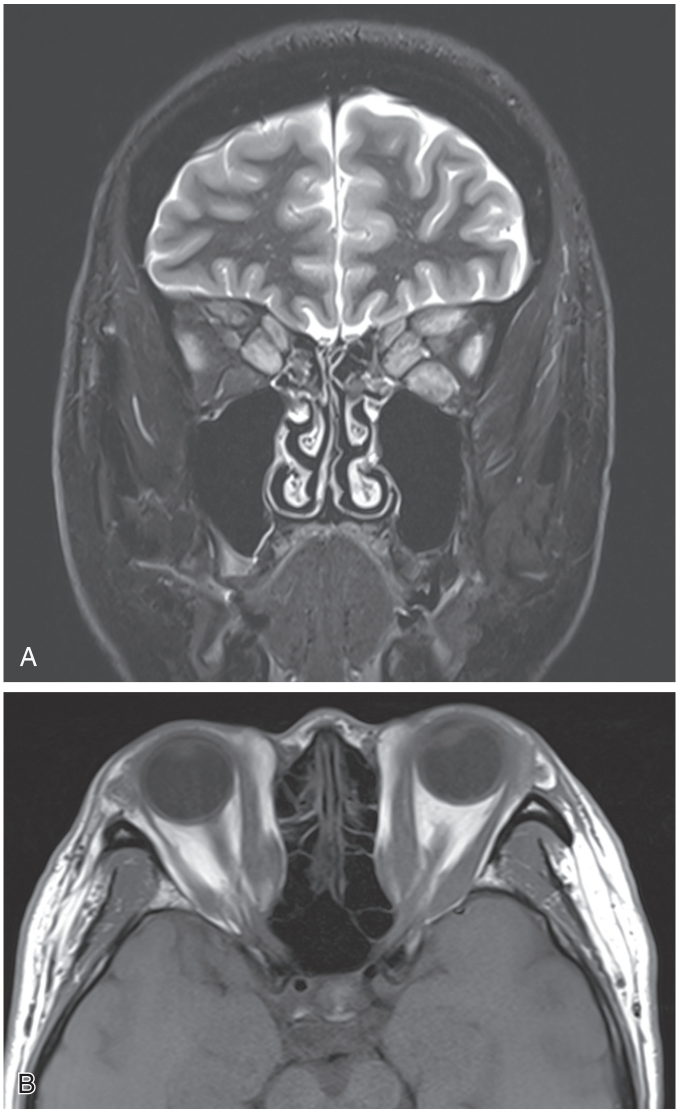

Fig. 72.6 Orbital Magnetic Resonance Imaging Scans of a 49-Year-Old With Left Dysthyroid Optic Neuropathy. **A,** Coronal T2-weighted short tau inversion recovery sequence image showing enlargement of all extraocular muscles, marked signal hyperintensity over bilateral rectus (except left inferior rectus) and superior oblique muscles, as well as bilateral apical crowding. Left orbit was more severely affected. **B,** Axial T1-weighted image, showing bilateral proptosis and apical crowding, which were more prominent over the left orbit.

Orbital computed tomography (CT) and magnetic resonance imaging (MRI) are the most commonly used imaging modalities in the evaluation of GO.[61,62] Compared with MRI, CT is quicker, more readily available, and much cheaper. CT provides simultaneous assessment of both bony and soft tissue structures, although it is less preferred in serial monitoring because of the radiation burden. In contrast, MRI offers superior resolution of orbital soft tissue, which is invaluable in the evaluation of disease activity and in the differential diagnoses of non-GO orbital diseases. Multiple MRI parameters, including short tau inversion recovery (STIR) sequence signal intensity ratio (SIR), T2-SIR, T1-SIR postgadolinium contrast, and apparent diffusion coefficient obtained from diffusion-weighted imaging, measure water content and vascularity of extraocular muscles (STIR-SIR of orbital fat as well), thus reflecting the degree of inflammatory edema[63-65] (Figs. 72.6A and B and Figs. 72.7). These measurements have been shown to correlate with CAS and response to treatment. They will be particularly helpful when CAS does not reliably reflect the actual disease activity (e.g., in patients with long disease duration,[66] darker complexion, or thicker skin).

Optical coherence tomography evaluates orbital structures affected by GO (e.g., retinal nerve fiber layer or choroidal thickness, optic nerve blood vessel density, size of rectus muscles), and the measurements may provide additional information regarding the disease status. Technetium-based scintigraphy is a novel modality that can potentially diagnose GO, assess disease activity and, reflect treatment response.[67]

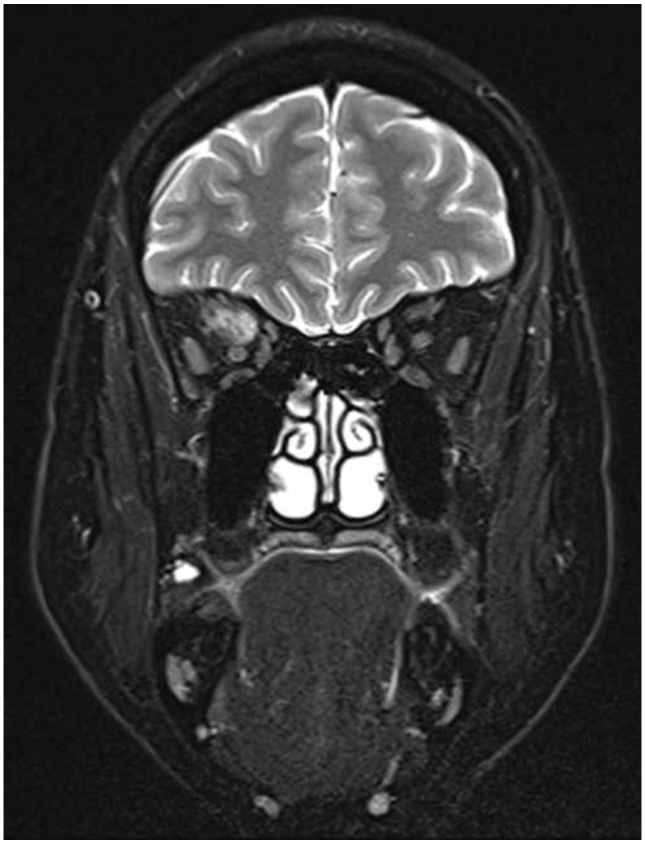

Fig. 72.7 Coronal T2-Weighted Orbital Magnetic Resonance Imaging of a 50-Year-Old With Active Moderate-To-Severe Graves' Orbitopathy, Revealing Markedly Asymmetrical Involvement With Isolated Enlargement and Signal Hyperintensity of Right Superior Rectus, Causing Downward Displacement of Right Optic Nerve.

Quality of Life Assessment

Significant impairment of QoL and psychological well-being has been well-recognized among GO patients, and the impact is evident across the whole disease spectrum. Patients with GO are more likely to require psychotherapy, more prone to develop mental features suggestive of underlying neuropsychiatric disorders, and at higher risk of death by suicide.[68] Clinical measures do not adequately predict physical and psychosocial functioning in daily life. Hence, EUGOGO recommends the use of a disease-specific questionnaire, Graves' Orbitopathy Quality of Life (GO-QoL), in routine clinical practice to assess and monitor the impact of the disease and its treatment on QoL and psychosocial well-being.[12] A recent systematic review concluded that GO-QoL was the best disease-specific QoL assessment tool, given its high validity, reliability, and cultural applicability.[69] A standard GO-QoL questionnaire and its scoring system are shown in Table 72.5. Originally developed in Dutch, GO-QoL is now available in 18 languages. All major treatment trials regarding GO over the past decade have included GO-QoL as one of the primary or secondary outcomes so that the benefits of certain interventions could be comprehensively evaluated.

Previous studies reported that certain demographic or clinical characteristics were associated with the visual functioning subscale (VFS) and the appearance subscale (AS) of the GO-QoL. Their results are inconsistent, probably because of the following confounders: (1) non-consecutive patient recruitment resulting in potential selection bias; (2) wide disease spectrum in the study population; (3) QoL assessed when the patients had not been rendered euthyroid; and (4) previous GO treatment may have altered QoL. Recently, a EUGOGO center performed a prospective follow-up trial, recruiting consecutive patients with active moderate-to-severe GO who were euthyroid and treatment-naïve before study inclusion.[68] The predictive factors for QoL at baseline and 6 months after standard intravenous GC treatment were studied using multivariate analysis. While increasing age, overall disease severity, and diplopia predicted worse baseline VFS score, CAS, upper lid retraction, and diplopia were associated with a worse VFS score post-treatment. Younger age, female gender, smoking history, and overall disease severity predicted worse baseline AS score, while only overall disease severity and upper lid retraction were associated with a worse AS score post-treatment. Both GO-QoL subscales significantly improved after treatment. It became evident that, while some demographic factors correlated with baseline QoL, the improved GO-QoL after treatment was exclusively associated with ophthalmic parameters. These findings suggest that treatment strategies that effectively ameliorate both disease activity and severity help optimize QoL in patients suffering from active moderate-to-severe GO.

KEY POINTS

- All patients with Graves' orbitopathy should undergo comprehensive clinical evaluation (disease activity and severity and quality-of-life assessment) and laboratory tests (thyroid function test and thyroid-stimulating hormone receptor antibody). Orbital imaging will be indicated in patients with atypical presentation or inconclusive clinical evaluation, as well as in preoperative planning.

MANAGEMENT

In this section, we will discuss the management of GO in terms of general measures which apply to all GO patients, specific pharmacological treatment, and the role of surgery in GO.

General Measures

Multidisciplinary Care. EUGOGO recommends referral of all GO patients (except for the mildest cases) to combined thyroid–eye clinics

TABLE 72.5 Graves' Orbitopathy Quality of Life Questionnaire

The following questions deal specifically with your thyroid eye disease. Please focus on the past week while answering these questions.

During the past week, to what extent were you limited in carrying out the following activities, because of your thyroid eye disease? (Questions 1-8)

Visual Functioning Subscale (VFS)	*1 point*	*2 points*	*3 points*
1. Bicycle (Skip if never learned to ride a bike)	*Yes, Seriously*	*Yes, a Little*	*No, Not at all*
2. Driving (Skip if no driver's license)			
3. Moving around the house			
4. Walking outdoors			
5. Reading			
6. Watching television			
7. Hobby or pastime			
8. During the past week, did you feel hindered from something that you wanted to do because of your thyroid eye disease?			

The following questions deal with your thyroid eye disease in general. (Questions 9-16)

Appearance subscale (AS)			
9. Do you feel that your appearance has changed because of your thyroid eye disease?	*Yes, Very Much So*	*Yes, a Little*	*No, Not at all*
10. Do you feel that you are stared at in the streets because of your thyroid eye disease?			
11. Do you feel that people react unpleasantly because of your thyroid eye disease?			
12. Do you feel that your thyroid eye disease has an influence on your self-confidence?			
13. Do you feel socially isolated because of your thyroid eye disease?			
14. Do you feel that your thyroid eye disease has an influence on making friends?			
15. Do you feel that you appear less often on photos than before you had thyroid eye disease?			
16. Do you try mask changes in appearance caused by your thyroid eye disease?			

- Calculation:
  - Total number of points scored in questions 1–8 = raw score for VFS (range 8-24); total number of points scored in questions 9–16 = raw score for AS (range 8–24)
  - Total score for VFS or AS (each range 0–100) = $100 \times (\text{raw score} - y)/2\,y$, where y represents the number of valid answers in each subscale.
  - For both VFS and AS, higher scores indicated better quality of life.

or specialized centers that provide endocrinological and ophthalmological expertise.[12] Early diagnosis and treatment are believed to have contributed to an increase in prevalence of mild and inactive disease since the implementation of the Amsterdam Declaration.[3,4] A UK survey demonstrated that significantly more patients who attended specialist GO clinics were satisfied with treatment than those who did not (67% vs. 52%, $P < .05$).

Smoking Cessation. The well-established harmful effects of smoking on GO are discussed in "Radioactive Iodine Therapy." According to a UK multicenter GO audit, only 63% of current smokers were offered smoking cessation advice, and only one-third of GO patients were aware of the deleterious effect of cigarette smoking on GO.[70] Physicians should urge all patients with Graves hyperthyroidism, irrespective of the presence/absence of GO, to refrain from smoking, if necessary with the help of specialized smoking cessation programs or clinics.

Thyroid Dysfunction. Prompt restoration and stable maintenance of euthyroidism are priorities in GO patients. As recommended by the European Thyroid Association, the first-line treatment of Graves hyperthyroidism is antithyroid drugs (ATDs).[71] Major guidelines favor the administration of ATDs as a titration regimen (T) instead of as a "block and replace" regimen (BR), which is associated with a higher rate of side effects.[71,72] Some argue that BR may be associated with more stable thyroid function, although there is little supportive evidence. In a recent EUGOGO prospective multicenter observational cohort study,[73] 344 patients with untreated Graves hyperthyroidism without overt GO were treated with either T ($n = 278$; 81%) or BR ($n = 66$; 19%) for 18 months. During the course of ATDs, the prevalence of euthyroidism was always higher in the T group than in the BR group (6 months: 47.8% vs. 24.5%, $P = .002$; 12 months: 81.4% vs. 58.2%, $P = .001$; 18 months: 85.6% vs. 62.7%, $P = .001$). There was no difference between both groups in TSH-R–Ab levels, which decreased significantly in all patients after treatment with ATDs. There was a trend of higher prevalence of *de novo* GO in the T group (17.8% vs. 9.1%, $P = .096$), although it was not statistically significant. It remains uncertain whether the choice of ATD regimen affects the risk of subsequent development of GO, or whether it alters the natural history of preexisting GO. Until larger randomized controlled trials (RCTs) resolve these issues, careful titration of either ATD regimen to maintain euthyroidism is essential for all GO patients, as both under- and overtreatment with ATDs will worsen GO. Likewise, clinicians should ensure adequate thyroid hormone replacement in patients with hypothyroid GO and watch out for emergence of thyroid dysfunction in those with euthyroid GO.

Regarding definitive treatments of Graves hyperthyroidism, thyroidectomy does not seem to affect the natural course of GO in the presence of adequate postoperative thyroid hormone replacement. However, RAI is a definite risk factor for progression or *de novo* occurrence of GO (discussed in "Radioactive Iodine Therapy"). The use of GC prophylaxis effectively reduces the risk. It is postulated that GCs work by blunting the surge in TSH-R–Ab levels, a well-documented phenomenon after RAI.[17] Apparently, patients with Graves hyperthyroidism for more than 5 years are not at increased risk of the

TABLE 72.6 Post–Radioactive Iodine Therapy Glucocorticoid Prophylaxis for Patients With Graves Hyperthyroidism

Indications According to Different Scenarios

Graves' orbitopathy (GO) status	*Other risk factors[a] present?*	*Radioactive iodone therapy (RAI) as one of the possible treatment options?*	*Glucocorticoid prophylaxis indicated?*	
			ATA 2016[b]	*ETA 2018[c]*
No pre-existing GO	No	Yes	No	No
No pre-existing GO	Yes	Yes	Insufficient data for recommendation	Yes
Inactive mild-to-severe GO	No	Yes	No	No
Inactive mild-to-severe GO	Yes	Yes	No	Yes
Active mild GO	No	Yes	Yes, consider risk-benefit ratio	Yes
Active mild GO	Yes	Yes	Yes	Yes
Active moderate-to-severe GO or sight-threatening GO		No, RAI should be avoided		

Regimens of Glucocorticoid Prophylaxis

Regimen	*Dosing*	*When to start?*	*Remarks*
Standard-dose oral prednisone	0.4–0.5 mg/kg body weight daily for 4 weeks, then taper over 8 weeks	1–3 days after RAI	• Most well-validated regimen
Low-dose oral prednisone	0.2–0.3 mg/kg body weight daily, reduce by 2.5–5 mg every 7–14 weeks, total 6 weeks	1 day after RAI	• Not consistently effective • Better reserved for low-risk patients (e.g., mild or absent GO)
Intravenous methylprednisolone	500 mg weekly for 2 weeks, then 250 mg weekly for 2 weeks	2 days after RAI	• Equally effective but associated with less insomnia and gastric symptoms when compared with standard-dose oral prednisone

[a] High serum thyroidstimulating hormone receptor antibody titer (>5-fold cutoff), acute or severe hyperthyroidism (high serum free T3 >3- to 5-fold), active smoking, recent-onset hyperthyroidism (duration <5 years), or delayed correction of post-RAI hypothyroidism.

[b] 2016 American Thyroid Association Guidelines for Diagnosis and Management of Hyperthyroidism and Other Causes of Thyrotoxicosis[53]

[c] 2018 European Thyroid Association Guideline for the Management of Graves' Hyperthyroidism[52]

adverse effects on GO, and GC prophylaxis may not be necessary in these patients.[17] The indications and regimens for GC prophylaxis are shown in Table 72.6.[15,71,72]

Local Treatment Modalities. GO patients frequently complain of dry eyes owing to tear film instability, which is caused by lacrimal gland dysfunction, proptosis, eyelid abnormalities, and impaired Bell's phenomenon. Frequent use of artificial tears (while awake) and lubricant ointments (before sleep) is essential for ocular surface protection. Lifestyle modifications (e.g., limiting screen time, avoiding prolonged reading or driving) should be advised to reduce excessive strain on the eyes. Wearing sunglasses may relieve photophobia and minimize ocular surface irritation (e.g., by wind). Prisms as temporary measures can reduce troublesome diplopia while awaiting more definitive correction by immunomodulatory treatment or rehabilitative surgery. Periocular injections of GCs or botulinum toxin may offer temporary control of eyelid retraction, extraocular muscle inflammation, and ocular dysmotility.

KEY POINTS

- All Graves' orbitopathy patients should be evaluated and managed in dedicated multidisciplinary thyroid–eye clinics, which improve patient outcomes and satisfaction. Smoking cessation, maintenance of stable euthyroidism, and local treatment are essential general measures.

Mild Graves' Orbitopathy

Selenium. The importance of selenium to thyroid physiology is reflected by the high concentration of selenium in the thyroid gland. Thyrocytes express several selenoproteins, including deiodinase isoenzymes, members of the glutathione peroxidase, and the thioredoxin reductases, which play important roles in thyroid hormone metabolism, antioxidative functions, and antiinflammatory functions.[74] In a cell culture study, preincubation with selenium (in the form of selenium-methylselenocysteine, SeMCys) abolished some of the adverse effects (cellular proliferation and secretion of proinflammatory cytokines) of hydrogen peroxide–induced oxidative stress on OFs from GO patients through an increase in glutathione peroxidase activity. SeMCys also reduced HA release, which was not augmented by hydrogen peroxide–induced oxidative stress, from OFs.[75] In a EUGOGO-led multicenter randomized placebo-controlled trial,[76] selenium administration (sodium selenite 100 μg twice daily for 6 months) resulted in improved QoL ($P < .001$), greater improvement in CAS ($P < .001$), higher likelihood of overall improvement ($P = .01$), and lower risk of disease progression ($P = .01$) in patients with mild GO. The better overall ophthalmic outcomes in the selenium group were mainly driven by improvement in eyelid aperture and soft tissue involvement, but not by changes in proptosis or ocular motility. The beneficial effects of selenium persisted for 6 months after treatment withdrawal. Hence, EUGOGO recommends 6-month selenium supplementation for patients with mild GO of relatively short duration because it improves eye manifestations and QoL, as well as prevents GO progression to more severe forms.[12] Although this European study was conducted in selenium-deficient geographical regions, the selenium status of individual patients was not evaluated. This has raised the question of whether the beneficial effects of selenium are explained by replacement of underlying deficiency or if they are independent of patients' baseline selenium status. Clinicians should also be aware that excessive selenium intake is associated with certain health hazards, for example, malignancy (skin cancer, prostate cancer), type 2 diabetes mellitus, and increased overall mortality.[74] A 2018 European Thyroid Association survey[77] showed that most respondents (94.1%) recommended selenium use in GO. Although nearly half of them (44.9%) also recommended selenium in addition to standard treatment in patients with moderate-to-severe GO, this approach has yet to be proven.

KEY POINTS

- Six-month selenium supplementation ameliorates and prevents progression of mild Graves' orbitopathy.

Active Moderate-to-Severe Graves' Orbitopathy

Intravenous Glucocorticoids. Systemic GCs have been the most commonly used immunosuppressants in the treatment of active moderate-to-severe GO, with good efficacy, since the 1950s. They achieve anti-inflammatory and immunomodulatory functions by: (1) interfering with the functions of B and T lymphocytes; (2) suppressing the recruitment and functions of immunocompetent cells; (3) inhibiting the release of proinflammatory mediators; and (4) decreasing the synthesis and secretion of glycosaminoglycans from activated OFs.[78] The molecular mechanisms underlying GC actions can be classified as genomic and non-genomic pathways. Through the genomic pathway, the lipophilic GCs bind to their intracellular receptor. The activated GC–receptor complex is then transported into the cell nucleus, where it dissociates and interferes with the transcription processes. The production of anti-inflammatory mediators is increased by transactivation of anti-inflammatory genes, whereas that of proinflammatory mediators is reduced through transrepression of proinflammatory genes. Although the genomic mechanisms take time to consolidate, the rapid effects of GCs, especially when given via an intravenous route, have been attributed to the non-genomic pathway. The non-genomic pathway modulates intracellular signaling through: (1) interacting with cytosolic receptors; (2) interacting with membrane-bound steroid receptors and their second messenger systems; and (3) stabilizing the cell membrane by intercalation, which ultimately disturbs the physiological course of affected cells (exclusively occurs during high-dose GC treatment).[78,79]

EUGOGO recommends high-dose intravenous GCs (IVGCs) as the first-line treatment for active moderate-to-severe GO.[12] IVGCs demonstrated superior efficacy (overall response rate 70%–80% vs. 50%) and safety profile (rate of adverse events 39% vs. 81%) than oral GCs (OGCs).[12] IVGCs substantially improved CAS, ocular dysmotility, visual acuity, and QoL,[68] but only had a limited benefit on proptosis. They are most effective and disease-modifying when given early during the active phase of the disease. Successful treatment was associated with reduced need for rehabilitative surgery in the long run.[80] The typical dosing regimens, monitoring schedule, and absolute contraindications of IVGCs are shown in Table 72.7. The overall morbidity and mortality associated with IVGCs were 6.5% and 0.6%, respectively.[78] Severe cardiovascular (e.g., acute coronary syndrome, stroke) and hepatic toxicities (e.g., acute hepatitis, acute liver failure) were uncommon but potentially fatal,[78] and current consensus suggests several precautions to minimize the risks of such events: (1) each single dose of IVGCs (as methylprednisolone) should not exceed 750 mg; (2) the cumulative dose of each IVGC course should not exceed 8 g; and (3) administration of IVGCs on consecutive days should be avoided.[12]

TABLE 72.7 Intravenous Glucocorticoid Use in Graves' Orbitopathy—Regimen, Monitoring and Absolute Contraindications

Regimen according to Graves' orbitopathy (GO) status	• Active moderate-to-severe GO
	  ◦ Intravenous methylprednisolone 500 mg weekly for six doses, then 250 mg weekly for six doses
	  ◦ Cumulative dose 4.5 g, 12-week course
	• Active moderate-to-severe GO with diplopia or severe proptosis
	  ◦ Intravenous methylprednisolone 750 mg weekly for six doses, then 500 mg weekly for six doses
	  ◦ Cumulative dose 7.5 g, 12-week course
	• Dysthyroid optic neuropathy ("hit hard and short")
	  ◦ Intravenous methylprednisolone 750 mg alternate day for seven doses (2 weeks), (if dysthyroid optic neuropathy resolves), then 500 mg weekly for five doses
	  ◦ Cumulative dose 7.75 g, 7-week course

Monitoring and Precautions	• Before treatment:
	  ◦ Check fasting blood glucose, liver function test, and markers for viral hepatitis
	  ◦ Ensure stable control of hypertension and diabetes mellitus if any
	• During treatment:
	  ◦ Monitor fasting blood glucose, liver function test, and blood pressure at least every other week
	  ◦ Observe for mood changes or mental disturbance
	• Adjunctive treatments:
	  ◦ Proton pump inhibitors (to prevent peptic ulcer) if needed

Absolute contraindications	• Recent viral hepatitis or significant hepatic dysfunction • Severe cardiovascular disease(s) • Uncontrolled severe hypertension or unstable diabetes mellitus • Active psychiatric disorders

Orbital Radiotherapy. Orbital radiotherapy (ORT) has been established as a treatment modality of GO since the 1970s, following a series of reports describing its clinical efficacy. The clinical benefit of ORT in GO is believed to be mediated through depleting radiosensitive lymphocytes that infiltrate the orbits and drive orbital inflammation.[79] ORT may also induce terminal differentiation of OFs, thus limiting their activation (e.g., secretion of GAG and proinflammatory mediators, *de novo* adipogenesis) and resulting in durable therapeutic effect.[81] The typical dosing regimen is a cumulative dose of 20 Gy per orbit fractionated in 10 daily doses given over a 2-week period,[12] but an alternative regimen of 1 Gy per week over a 20-week period was shown to be equally effective and better tolerated.[82]

A recent comprehensive review has summarized the clinical efficacy of ORT.[81] ORT and OGC demonstrated similar efficacy as initial treatment of GO, but ORT was better tolerated. There has been ample evidence since the 1980s that the combination of ORT and OGC is more efficacious than either therapy alone. However, a recent multicenter, double-blind, RCT showed that concurrent ORT did not have added benefit in patients receiving a 24-week course of OGC.[83] In general, patients with a shorter duration of GO before treatment and with active moderate-to-severe disease were more likely to benefit from ORT, compared with those with long disease duration and mild inactive disease. ORT mainly improved ocular dysmotility and soft tissue involvement, while the effect on proptosis was limited. In addition, retrospective case series supported the disease-modifying role of ORT in the management of GO. ORT-GC combination lowered the risk of disease reactivation and developing DON compared with GC monotherapy in patients with active moderate-to-severe GO[84,85] and helped eliminate the need for urgent orbital decompression in patients with GC-responsive DON.[86] ORT given during the active phase of GO was also associated with better outcomes after rehabilitative orbital decompression, including greater improvement in proptosis and lower risk of postoperative increase in extraocular muscle volume, as well as diplopia.[87,88] Most clinical evidence of ORT-GC combination in active moderate-to-severe GO was based on patients who received OGC or an IVGC/OGC combination. There has not been any prospective randomized trial evaluating whether ORT offers additional benefit on top of standard IVGC therapy. In a retrospective study comparing ORT-IVGC and IVGC monotherapy (median cumulative dose in both groups 1.6–1.9 g only) in patients with active moderate-to-severe GO, ocular dysmotility improved only in the combination group, which also demonstrated more frequent overall ophthalmic improvement and lower risk of disease reactivation, compared with IVGC monotherapy.[89]

Overall, ORT is safe, without major safety concerns. Transient conjunctivitis and periorbital skin irritation may occur. Large retrospective studies showed no increased risk of cataract formation compared with nonirradiated GC-treated GO patients or normal controls.[90,91] Long-term follow-up analyses did not reveal any cancer within the radiation field nor increased risk of radiation-induced cancer death compared with the general population.[92,93] Nonetheless, ORT should be avoided in patients below the age of 35 years, in view of the theoretical risk of carcinogenesis.[79] Coexisting diabetes mellitus and hypertension were associated with the development of retinopathy after ORT, which could be solely radiation-induced or represent progression of underlying diabetic or hypertensive retinopathy.[90,91] Hence, ORT is contraindicated in patients with diabetic or hypertensive retinopathy.[79]

Glucocorticoid-Resistant, Active, Moderate-to-Severe Graves' Orbitopathy. If patients with active GO show no or only partial response to first-line IVGC therapy, EUGOGO recommends several second-line treatment options, namely a second course of IVGCs (as long as patients can tolerate it, with a normal liver function test), OGC-ORT combination, OGC-cyclosporin combination, and rituximab.[12] Although these strategies are efficacious in treatment-naïve cases, no prospective randomized trial has examined their role in patients resistant to IVGCs. Persistently high CAS may sometimes be caused by orbital congestion instead of active inflammation. Orbital decompression will provide rapid relief of congestion, which is usually resistant to immunomodulation. MRI may help distinguish between the two clinically similar conditions. Management for these difficult cases should be individualized, with detailed discussion between the multidisciplinary team and patients. Novel treatment approaches (see below) are potential solutions and will be elaborated in a later section.

Sight-Threatening Graves' Orbitopathy

Dysthyroid Optic Neuropathy. DON is the most common form of sight-threatening GO. Prompt recognition and timely treatment are essential in restoring optic nerve function. IVGC therapy was superior to orbital decompression as upfront treatment in terms of resolution of DON (response rate 56% vs. 17%) based on a small randomized clinical trial.[94] EUGOGO recommends high-dose IVGCs as the first-line treatment of DON if not contraindicated[12] (Table 72.7). If features of DON persist after 2 weeks of IVGCs, prompt orbital decompression should be performed to prevent irreversible visual loss. Urgent surgery can be avoided in up to 40% to 50% of DON cases after IVGCs.[10,95] The presence of optic disc swelling at diagnosis,[95] persistently active disease at 2 weeks after IVGCs,[95] and DON attributed to optic nerve stretch[96] predicted GC unresponsiveness, and patients with the above features will benefit from early orbital decompression. In a retrospective study, 104 patients with GC-responsive DON received ORT, and 94% of them did not require urgent orbital decompression. Therefore, ORT concurrent with IVGC therapy may prevent recurrent DON after GC withdrawal.[86]

KEY POINTS

- Intravenous glucocorticoid (IVGC) is the standard treatment for active moderate-to-severe Grave orbitopathy and dysthyroid optic neuropathy (DON). Orbital radiotherapy may further improve overall response (especially in ocular dysmotility) and prevent disease reactivation or progression. Urgent orbital decompressive surgery is indicated in IVGC-resistant DON.

Corneal Breakdown and Other Forms of Sight-Threatening Graves' Orbitopathy

Approximately 16% of GO patients develop corneal involvement.[3] They are at risk of corneal damage, especially when lagophthalmos and poor Bell's phenomenon coexist, meaning that the normal corneal protective mechanisms are defective. Corneal breakdown is a medical emergency that warrants immediate intensive treatment, including frequent topical lubricants and antibiotics, moisture chambers, and other temporary measures to improve eyelid closure (e.g., blepharroraphy, tarsorraphy, amnion membranes, botulinum toxin, emergency gluing). Corneal grafting may be necessary in case of irreversible damage. After the above acute management, permanent measures to improve eyelid closure are essential to prevent recurrent exposure keratopathy and corneal breakdown.

Urgent orbital decompression is indicated if other rare forms of sight-threatening GO are present, including globe subluxation (sudden anterior displacement of the globe with eyelid retraction behind the equator of the globe), choroidal folds (indentation on the globe by enlarged extraocular muscles), and postural visual darkening (borderline optic nerve perfusion because of high intraorbital pressure aggravated by transient fall in systolic blood pressure on upright posture[97]).

Inactive Graves' Orbitopathy and the Role of Rehabilitative Surgery

Despite successful immunomodulatory therapies leading to inactivation of the disease, GO patients may continue to suffer from disfigurement and disability owing to irreversible orbital tissue remodeling. Rehabilitative surgery aims at correcting disfigurement and restoring visual function during the inactive post-inflammatory phase, when pharmacological treatments have a limited disease-modifying role. GO should remain inactive and stable for at least 6 to 8 months before rehabilitative surgery is considered; otherwise, ongoing inflammation and tissue remodeling may render surgery ineffective. There are three main types of rehabilitative surgery: (1) orbital decompression, which reduces proptosis by removing orbital bone or adipose tissue; (2) eye muscle surgery, which ameliorates squint and diplopia; and (3) eyelid surgery, which corrects the abnormal eyelid position. If patients require more than one type of procedure, orbital decompression should be the first step, followed by eye muscle surgery, and then finally eyelid surgery. The rationale behind this sequence is that orbital decompression may cause deterioration in ocular dysmotility because of displacement of orbital soft tissue, and vertical squints may influence the optimal eyelid position. Rehabilitative surgery effectively improves patients' visual functioning, appearance, and overall QoL.[69]

Novel Treatment Approaches for Immunosuppression in Graves' Orbitopathy

Limitations of Current Therapy. IVGC is currently the standard of care in active GO, but approximately 20% to 30% of cases will have persistently active disease despite standard treatment. On the other hand, some patients develop disease reactivation after steroid withdrawal. A recent randomized trial that evaluated IVGC efficacy by a more stringent and comprehensive composite outcome found an overall response rate of 50% only (compared with 70%–80% in older studies) and a relapse rate of around 10%.[98] Disease severity (e.g., proptosis, diplopia, ocular dysmotility) tends to be less responsive to IVGCs compared with disease activity. Residual functional impairment, impaired QoL, and the requirement for rehabilitative surgery may therefore persist despite standard treatment. Severe toxicities and treatment-related mortality associated with IVGCs are uncommon but non-negligible. Novel treatment strategies for active moderate-to-severe GO that address some of the above limitations have emerged over the past decade.[29,36,39] The key findings from representative RCTs are discussed later and summarized in Table 72.8.

TABLE 72.8 **Summary of Key Randomized Controlled Trials on Novel Treatment Approaches of Graves' Orbitopathy**

Therapeutics	Mechanism of Action	Study Design/Patient population	Key Outcomes	Results (intervention vs. control group)
Mycophenolate mofetil[80]	Dual antiproliferative effect on both B- and T-cells	• Single-center RCT • 174 euthyroid patients with active moderate-to-severe GO • MMF 1 g daily vs. glucocorticoid therapy (both for 24 weeks)	**Primary** • Response rates at weeks 12 and 24 (improvement in ≥3 parameters of the composite index without deterioration in any objective parameters)	• Week 12: 79% vs. 51% • Week 24: 91% vs. 68%
Mycophenolate sodium[78]	Dual antiproliferative effect on both B- and T-cells	• Multicenter RCT • 164 euthyroid patients with active moderate-to-severe GO • MPS 720 mg daily (24 weeks) plus weekly IVGC (12 weeks) vs. weekly IVGC (12 weeks) alone	**Primary** • Response rate at week 12 (improvement in ≥2 parameters of the composite index without deterioration in any parameters) • Relapse rates at weeks 24 and 36 **Post hoc** • Response rate at week 24 • Sustained response at week 36 • GO-QoL scales	• No significant difference between groups • 71% vs. 53% • 67% vs. 43% • No significant difference between groups
Rituximab[83]	B-cell depletion	• Single-center RCT • 32 euthyroid patients with active moderate-to-severe GO • RTX (2 g/500 mg IV) vs. weekly IVGC (12 weeks with cumulative dose 7.5 g)	**Primary** • Decrease of CAS of ≥2 points or disease inactivation (CAS <3) at week 24 **Secondary** Improvement in severity signs (NOSPECS W class, proptosis and lid width, eye motility) • GO reactivation • Percentage of patients requiring surgical procedures after 12 months • GO-QoL scales	• 100% vs. 69% • Better ocular motility in RTX group • 0% vs. 33% • 33% vs. 75% • Visual functioning scores improved significantly in RTX group only
Rituximab[84]	B-cell depletion	• Single-center RCT • 25 euthyroid patients with active moderate-to-severe GO • RTX (2 g IV) vs. placebo	**Primary** • Decrease of CAS (assessed as a continuum and separately as an improvement by ≥2 points) at week 24	• No significant difference between groups in both primary and all secondary outcomes
Tocilizumab[100]	Anti-IL-6 receptor MAb	• Multicenter RCT • 32 euthyroid patients with glucocorticoid-resistant active moderate-to-severe GO • TCZ (8 mg/kg IV once every 4 weeks for 4 doses) vs. placebo	**Primary** • Decrease of CAS of ≥2 points at week 16 **Secondary/post hoc** • Decrease of CAS of ≥2 points at week 40 • CAS <3 at weeks 16 and 40 • Disease severity • GO-QoL scales	• 93% vs. 59% • 87% vs. 59% • Week 16: 87% vs. 35% • Week 40: 80% vs. 47% • No significant improvement of proptosis and diplopia in TCZ group • More patients in TCZ group reported improvement in GO-QoL (47% vs. 35%)

TABLE 72.8 Summary of Key Randomized Controlled Trials on Novel Treatment Approaches of Graves' Orbitopathy—cont'd

Therapeutics	Mechanism of Action	Study Design/Patient population	Key Outcomes	Results (intervention vs. control group)
Teprotumumab[103,104]	Anti-IGF1-R blocking MAb	• Two multicenter RCTs • 170 euthyroid patients with active moderate-to-severe GO in total • TPT (once every 3 weeks for 8 IV infusions; first dose 10 mg/kg, remaining seven doses 20 mg/kg)	• Overall responders (reduction of ≥2 points in CAS and reduction of ≥2 mm in proptosis) at week 24 • CAS of 0 or 1 • Reduction of ≥2 mm in proptosis • Diplopia response • GO-QoL scales	• 73% vs. 14% • 62% vs. 22% • 77% vs. 15% • 68% vs. 27% • TPT group reported higher scores and greater improvement in overall, visual functioning, and appearance scores

RCT, Randomized controlled trial; *GO*, Graves' orbitopathy; *MMF*, mycophenolate mofetil; *MPS*, mycophenolate sodium; *IVGC*, intravenous glucocorticoid; *GO-QoL*, Graves' orbitopathy quality of life questionnaire; *RTX*, rituximab; *IV*, intravenous; *CAS*, clinical activity score; *MAb*, monoclonal antibody; *TCZ*, tocilizumab; *IGF1-R*, insulin-like growth factor-1 receptor; *IV*, intravenous; *TPT*, teprotumumab

Mycophenolate. Pathophysiological basis and mechanisms of actions: Mycophenolic acid (MPA) inhibits inosine monophosphate dehydrogenase (IMPDH), which catalyzes the rate-limiting step in *de novo* synthesis of guanosine nucleotides in activated lymphocytes, and therefore exerts dual antiproliferative action on both B- and T-cells. In addition, *in vitro* studies suggest that MPA is capable of inhibiting fibroblast proliferation and function via both IMPDH-dependent and -independent (e.g., PI3K/mTOR) pathways. MPA is clinically available as mycophenolate mofetil (MMF) and enteric-coated mycophenolate sodium (MPS).

Clinical efficacy, safety, and therapeutic application: A single-center RCT demonstrated that MMF was superior to GC monotherapy (both for 24 weeks) in terms of overall response and individual ophthalmic parameters (e.g., soft tissue involvement, diplopia, proptosis)[99] (Table 72.8). A subsequent EUGOGO multicenter RCT compared standard 4.5 g weekly IVGC alone and IVGC with MPS for 24 weeks[98] (Table 72.8). The combination group achieved a higher overall response rate at week 24 and a higher sustained response rate at week 36, as well as more significant improvement in individual ophthalmic components (including CAS and its components, vertical ocular dysmotility, and visual functioning subscale of GO-QoL). Several important differences in baseline characteristics between the two study populations (higher mean age, more prevalent smoking, longer disease duration, and greater proportion of TSH-R–Ab–positive patients) possibly explain the lower response rates in the EUGOGO trial.[100] Low-dose mycophenolate use in GO is generally safe.[100] Mild gastrointestinal intolerance was slightly more prevalent among mycophenolate-treated patients. Compared with IVGC monotherapy, combination treatment did not result in increased risk of major toxicities, including serious infection, hepatotoxicity, cytopenia, and treatment-related mortality. Therefore, IVGC-mycophenolate combination will potentially supplant IVGC monotherapy as the first-line treatment of active moderate-to-severe GO, in view of its superior efficacy and reassuring safety profile.

Rituximab. Pathophysiological basis and mechanisms of actions: Rituximab (RTX), a chimeric murine/human monoclonal antibody targeting CD20, results in rapid depletion of both peripheral B-cells and intraorbital B-/T-cells.[22] As the clinical improvement of GO after RTX does not always correlate with the reduction in TSH-R–Ab level, the efficacy of RTX is probably explained by elimination of other B-cell functions apart from autoantibody production (e.g., cytokine production, antigen presentation, B-/T-cell costimulation, etc.).[24]

Clinical efficacy, safety, and therapeutic application: Two RCTs examined the role of RTX in active moderate-to-severe GO, but they produced grossly conflicting results (Table 72.8). In the Italian trial,[101] RTX demonstrated superior efficacy compared with weekly IVGC therapy in terms of disease inactivation, ocular dysmotility, and requirement of subsequent rehabilitative surgery. In contrast, the US trial[102] failed to show any difference between RTX and placebo. A subsequent joint *post hoc* analysis suggested that several differences in baseline characteristics (younger age, lower TSH-R–Ab levels, shorter duration of GO) may have accounted for the positive treatment outcomes in the Italian trial.[25] A few RTX-treated patients in these two RCTs developed transient deterioration in proptosis or visual loss, and even frank DON. It is postulated that massive lysis of intraorbital lymphocytes because of RTX therapy may cause cytokine release syndrome, with subsequent edema and expansion of orbital tissues, leading to progression of subclinical DON.[100] EUGOGO recommends RTX as one of the second-line treatment options after failure of IVGCs, but it is best avoided in patients with impending DON or long duration of disease.[12] This recommendation is in keeping with the conclusions of several recent retrospective studies.[103-105]

Tocilizumab. Pathophysiological basis and mechanisms of actions: IL-6 is a potent proinflammatory cytokine implicated in the pathogenesis of multiple autoimmune disorders. Activated GO OFs produced multiple chemoattractants, including IL-6, that support B-cell differentiation and synthesis of autoantibodies.[106-108] Although TSH-R activation enhanced the expression of IL-6 in GO OF/adipocytes, IL-6 in turn stimulated TSH-R expression in these orbital target cells.[109,110] IL-6 suppressed regulatory T-cell induction while promoting the development and functions of Th17 cells, a recently identified CD4+ T-cell subset that plays an important pathogenic role in GO.[111-113] GD patients with GO had higher serum levels of IL-6 than those without GO.[114] Greater lacrimal levels of IL-6 were also evident in GO patients compared with healthy controls.[115,116] Therefore, antagonizing the IL-6 pathway with tocilizumab (TCZ), a fully human IgG1 anti-IL6 receptor monoclonal antibody, represents a sound strategy in GO.

Clinical efficacy, safety, and therapeutic application: A small RCT evaluated the efficacy of TCZ versus placebo in patients with GC-resistant active moderate-to-severe GO[117] (Table 72.8). Significantly more patients in the TCZ group achieved improvement in CAS and disease inactivation, but not in proptosis or diplopia. Multiple preliminary reports and recent retrospective series[118,119] have also described the efficacy of TCZ in GC-resistant or -dependent cases. TCZ is overall safe and well-tolerated. The remarkable anti-inflammatory action of TCZ in active GO holds great promise, although larger clinical trials are needed to confirm its benefits and precisely define its role in GO management.

Teprotumumab. Pathophysiological basis and mechanisms of actions: The role of IGF-1R in the pathogenesis of GO has been discussed in the section "Thyroid Stimulating Hormone Receptor and Insulin-Like Growth Factor-1 Receptor Crosstalk." *In vitro* studies showed that blocking IGF-1R inhibited activation of OFs and fibrocytes. Teprotumumab (TPT) is a fully human IgG1 monoclonal blocking antibody that binds to the extracellular portion of IGF-1R and blocks its activation and signaling by endogenous ligands (IGF-1 and IGF-2). TPT also leads to near-complete internalization and degradation of IGF-1R on the cell surface. Once developed as an anticancer therapy, TPT has been subsequently repurposed for potential use in GO based on preclinical data.

Clinical efficacy, safety, and therapeutic application: The efficacy and safety of TPT versus placebo in treatment-naïve, active, moderate-to-severe GO were evaluated in two multicenter RCTs with similar trial design.[120,121] The primary endpoint of the initial phase II study[120] was a composite of reduction of at least 2/7 in CAS and a reduction of at least 2 mm in proptosis at week 24, whereas the subsequent phase III study[121] only focused on reduction in proptosis as the primary endpoint. The key findings of both studies are jointly summarized below. Approximately 70% of TPT-treated patients (~20% in the placebo group) achieved significant improvement in CAS, proptosis, or both. In particular, the proptosis response was both rapid (evident by week 6 in most responders) and marked (mean reduction of 3 mm, comparable to that achieved by single-wall orbital decompression). Furthermore, a 4-mm reduction in proptosis was achieved in 40% of the TPT group (phase II), and 72% of overall responders (phase II) were graded as having high response (reduction of at least 3 mm in proptosis and reduction of at least 3/7 in CAS). Significant improvement in diplopia and GO-QoL was also achieved in the TPT group. Patients in the phase III study who did not respond or relapse could enter an open-label extension study and receive second course of TPT. The follow-up and extension studies are currently ongoing. TPT was generally well tolerated, and the only significant side effect was hyperglycemia, which occurred in 7% of patients who received TPT. It mainly affected those with pre-existing diabetes mellitus and was easily managed with adjustment in antidiabetic medications.

In view of its impressive all-round efficacy (in terms of disease activity, severity, and QoL) and favorable safety profile, TPT has become the first pharmacotherapy approved by the US Food and Drug Administration for the treatment of adult GO since January 2020. Although there has been heated debate on whether TPT should replace IVGCs as the first-line treatment in active GO,[122] several issues of concern have to be adequately addressed before we incorporate TPT in our routine clinical practice[123]: (1) lack of long-term efficacy and safety data for TPT, including head-to-head comparison with IVGCs; (2) restricted availability (currently only commercially available in the United States); and (3) the unaffordability of TPT for most patients.

KEY POINTS

- Mycophenolate enhanced treatment efficacy of intravenous glucocorticoids. Tocilizumab is potentially useful in glucocorticoid-resistant active Graves' orbitopathy (GO). Teprotumumab resulted in marked improvement of active GO, in terms of both disease activity and severity.

BRIEF NOTE ON GRAVES DERMOPATHY AND THYROID ACROPACHY

Graves dermopathy (most commonly pretibial myxedema [PTM]) and thyroid acropachy are rare extrathyroidal manifestations of GD. According to case series that recruited patients before the twenty-first century, PTM occurs in 4% of patients with GO and in 13% of those with severe GO. Overall, PTM and thyroid acropachy affect approximately 1.5% and 0.3% of GD patients, respectively. Thyroid acropachy almost always occur in association with GO and Graves dermopathy, and PTM is associated with thyroid acropachy in 20% of cases.[124,125] However, prospective observational studies by EUGOGO reveal a significant reduction in the prevalence of Graves dermopathy in patients with GO, from 6% in 2010 to 0.7% in 2012.[3] The contemporary estimated prevalences of Graves dermopathy associated with GO and thyroid acropachy associated with GO in Europe are 0.15 and 0.03 per 10,000 population, respectively (compared with 10 for GO).[1] In general, PTM and acropachy share similar risk factors as GO. Local mechanical factors, for instance trauma or surgery and dependency (which may be aggravated by obesity) of lower extremities, also predispose to the development of PTM in susceptible patients.

Graves dermopathy most commonly affects the pretibial area in a symmetrical manner, with a raised waxy appearance similar to orange skin. Lesions in unusual sites are usually secondary to local trauma. Diffuse nonpitting edema or plaque forms are typical, but nodular or elephantiasic forms can occur. The lesions are usually asymptomatic but can be painful or pruritic occasionally. Thyroid acropachy is characterized by digital clubbing alone in most cases. Less commonly the presence of digital swelling and periosteal reaction of underlying bones constitute the full form, resembling hypertrophic pulmonary osteoarthropathy. The diagnosis of Graves dermopathy and thyroid acropachy is usually clinical, and biopsy is rarely needed. The histology of dermopathy reveals accumulation of GAG and mucin-like substances in the reticular dermis, together with marked edema similar to that of GO.

Smoking cessation should be strongly advised. Weight reduction in obese patients may improve PTM owing to reduction in venous stasis and dependency effect. Specific treatment of Graves dermopathy is indicated if symptomatic or raising cosmetic concerns. Local GC therapy in the form of topical GCs under occlusive dressing or intralesional injections can induce remission of cutaneous lesions and possibly prevent fibrosis or lymphatic obstruction. Systemic immunosuppressive therapies employed in active GO can also improve dermopathy. A recent case series reported that the administration of RTX or intravenous immunoglobulin resulted in improvement or stabilization of PTM.[126] Thyroid acropachy usually does not require any specific treatment. Long-term remission appears to be determined by the disease severity at presentation, instead of the effect of specific treatment.

SUMMARY AND PERSPECTIVES

Over the past two decades, we have witnessed remarkable advances in the understanding and clinical management of GO. It is reasonable to recommend the combination of IVGCs and mycophenolate as the new standard of care in active moderate-to-severe GO, in view of its practicability and superior efficacy to conventional treatment. Other combinations of widely available and affordable therapies may also be beneficial in GO, (e.g., IVGC-ORT [ongoing trial: ClinicalTrials.gov: NCT02339142] and IVGC with RTX or methotrexate).[36] Biologics (e.g,. TCZ, TPT) appear highly promising both in treatment-naïve and -resistant cases, although long-term efficacy and safety data are still pending. The roles of other existing targeted therapies in GO are also worth exploring (e.g., anti-IL23 or anti-IL17 agents for the IL-23/IL-17/Th17 axis, sirolimus for the mTOR pathway). Furthermore, several novel therapeutic agents can potentially treat Graves hyperthyroidism and associated orbitopathy simultaneously by targeting their shared immunological mechanisms (e.g., antigen-specific immunotherapy ATX-GD-59; anti-CD40 monoclonal antibody iscalimab; TSH-R antagonists).[36] Nonetheless, all new treatments should be carefully examined in RCTs (vs. placebo and/or standard of care), preferably with standardized primary and secondary outcomes, to draw sound conclusions on the efficacy of certain intervention and facilitate comparisons among different trials.[127] Therapeutic advances will continue to optimize clinical care of GO patients in a holistic manner.

INTRODUCTION: CONCEPT AND DEFINITION OF THYROIDITIS

The term "thyroiditis" refers to several generally benign thyroid disorders with the common feature of some form of inflammation of the thyroid gland, which may sometimes be accompanied by thyroid function perturbations. Its clinical spectrum may vary from an absence of clinically evident inflammation, apart from a biochemical thyroid dysfunction or goiter, to significant symptomatic subtypes, with acute pain and overall illness. The terminology used in thyroid autoimmune disorders may sometimes insufficiently reflect our knowledge on their physiopathology, and even regard as opposites diseases that are truly part of the same spectrum, for instance Hashimoto's thyroiditis (HT) and Graves' disease (GD). In any case, information regarding its pathogenesis is still being revealed.

Thyroidites have been classified according to different criteria, including known or suspected etiology, pathology, the existence of pain and tenderness, or the effect on thyroid function.

KEY POINTS

- The term "thyroiditis" refers to some form of thyroid inflammation with variable repercussions for thyroid function.
- Thyroidites are classified according to their etiology, pathology, the existence of pain, or the effect on thyroid function.
- The clinical course of subacute thyroiditis frequently fluctuates. The characteristic sequence involves an initial thyrotoxic phase, followed by hypothyroidism and eventual normalization.
- The presence of pain, the clinical course, evaluation of thyroid peroxidase antibody levels, erythrocyte sedimentation rate, white blood cell count, and thyroid hormones, as well as thyroid ultrasound and radioactive iodine uptake, are the mainstay for the differential diagnosis between the different subtypes of thyroiditis.

This chapter reviews the different subtypes of thyroiditis, with special reference to autoimmunity as the main cause of their development.

TABLE 73.1 Terminology for Thyroiditis

Type	Synonyms
Hashimoto's thyroiditis	Chronic lymphocytic thyroiditis Chronic autoimmune thyroiditis Lymphadenoid goiter
Postpartum thyroiditis	Painless postpartum thyroiditis Subacute lymphocytic thyroiditis
Painless sporadic thyroiditis	Silent sporadic thyroiditis Subacute lymphocytic thyroiditis Lymphocytic thyroiditis with spontaneously resolving hyperthyroidism
Painful subacute thyroiditis	Subacute de Quervain's thyroiditis Subacute nonsuppurative thyroiditis Giant-cell thyroiditis Subacute granulomatous thyroiditis Pseudogranulomatous thyroiditis
Suppurative thyroiditis	Infectious thyroiditis Acute suppurative thyroiditis Pyrogenic thyroiditis Bacterial thyroiditis
Drug-induced thyroiditis	Amiodarone, lithium, IFN-α, IL-2, tyrosine kinase inhibitors, checkpoint inhibitor immunotherapy
Radiation-induced thyroiditis	
Palpation- or trauma-induced thyroiditis	
Riedel's thyroiditis	Fibrous thyroiditis IgG4-induced thyroiditis

SUBTYPES OF THYROIDITIS

One of the main concerns when referring to thyroiditis is the controversy regarding the nomenclature used to categorize the different forms. However, in general, there is agreement on the use of several synonyms for equivalent entities (Table 73.1).

Most classifications categorize the different forms of thyroiditis according to the presence of thyroid pain and tenderness. In this regard, de Quervain's subacute thyroiditis (SAT), suppurative thyroiditis, radiation-induced thyroiditis, and palpation- or trauma-induced thyroiditis may involve pain to different extents, while the rest are generally clinically asymptomatic.[1] Table 73.2 summarizes the main differential characteristics between the various subtypes of thyroiditis, which will be discussed in detail in the corresponding sections. A frequent feature regarding the clinical course in thyroiditis is fluctuation; in this regard, painless postpartum thyroiditis, painless thyroiditis, and painful de Quervain's SAT may exhibit a characteristic sequence, which may involve thyrotoxicosis, hypothyroidism, or both (Fig. 73.1). On the contrary, although an initial euthyroid, or even slightly hyperthyroid, phase may occur in HT, the most frequent laboratory finding in this case is chronic hypothyroidism.

KEY POINTS

- Hashimoto's thyroiditis is a chronic autoimmune inflamatory infiltrate of the thyroid gland, with destruction of thyroid follicular cells, in the setting of thyroid auto-antibodies.

HASHIMOTO'S THYROIDITIS

Definition and Incidence

The term HT, or chronic autoimmune thyroiditis, implies an inflammatory infiltrate of the thyroid gland, destruction of thyroid follicular cells, and the presence of thyroid antibodies, mainly against thyroid peroxidase (TPOAb). It is a long-term and lifelong autoimmune disease in which the thyroid gland enlarges and often atrophies, leading to hypothyroidism.

Hakaru Hashimoto's, in 1912, was the first to report four patients with diffuse goiter and outline four histologic characteristics: diffuse lymphocytic infiltration, formation of lymphoid follicles, destruction of epithelial cells, and proliferation of fibrous tissue.

The term "Hashimoto's disease" or HT is sometimes used to refer only to goitrous thyroiditis, but it is usually considered to be a broad synonym for chronic thyroiditis or autoimmune thyroiditis, including atrophic and nongoitrous thyroiditis.

Hashimoto's disease is the world's most frequent cause of hypothyroidism in iodine-sufficient conditions. Overall, the disorder may affect up to 2% of the general population, is more common in older women, and is ten times more frequent in women than in men; in fact, 3% to 10% of women have been described as exhibiting chronic autoimmune thyroiditis.[2,3]

KEY POINTS

- Hashimoto's thyroiditis (HT) is a chronic autoimmune thyroiditis with thyroid inflammatory infiltration, destruction of thyroid follicular cells, and positivity for thyroid antibodies.
- HT is the most frequent cause of hypothyroidism on iodine-replete areas.
- Positivity for thyroid peroxidase antibody levels is the hallmark for diagnosis of HT.
- Several environmental and existential factors may trigger the onset of aberrant immune mechanisms in genetically predisposed individuals that eventually lead to autoimmune thyroid disease.

KEY POINTS

- Autoimmune thyroid disease is triggered and perpetuated due to a complex reciprocal relationship between humoral and cellular mechanisms.

TABLE 73.2 Main Differentiating Characteristics Between the Different Subtypes of Thyroiditis

	Etiology	Epidemiology	Clinical picture	Diagnosis	Treatment
Acute, suppurative	Infection (bacterial most frequent)	Prior upper respiratory infection No difference between sexes Children and 20–40 y. Association to pyriform sinus fistula	Sudden, local symptoms (pain, swelling, dysphagia, etc.) Generalized symptoms (fever) Mild thyrotoxicosis very rare	↑ESR. ↑WBC. TSH/FT4 normal TPOAb and TgAb negative FNA (gram-positive staining) and culture	Antibiotics FNA and/or drainage
Painful, subacute (de Quervain's)	Viral (almost)	Female predominance (5:1) 20–60 y. Possible seasonal incidence related to prior viral infection. Associated with HLA-B35	Prodromal generalized symptoms (flulike) Local pain, extending to jaw and ears Initial hyperthyroid phase followed by hypothyroidism	↓TSH/↑FT4. ↑↑ESR, ↑CRP Negative TPOAb and TgAb. ↓RAIU FNA: inflammatory infiltrate (+ giant cells) Biopsy: inflammatory infiltrate (+ giant cells), granulomas > fibrosis	NSAID, especially aspirin 1–3 g/day. Glucocorticoids Beta-blockers
Painless, silent, subacute	Autoimmune Postpartum	Female predominance (2:1) All ages, peak 30–40 y. Thyroid "aggressors" Potential progression to chronic	Initial hyperthyroid phase followed by hypothyroidism. No local symptoms	Abnormal TSH/FT4 ↑Thyroglobulin. (+) TPOAb and TgAb (persistent) (-) TSH-R–Ab. Normal inflammation reactants ↓RAIU	Expectant (observation) Beta-blockers for hyperthyroid symptoms L-T4 replacement therapy if needed
Chronic (Hashimoto's)	Autoimmune	Middle-aged women Thyroid dysfunction precipitating factors	Goiter in the early phase Later hypothyroidism	Initial goiter and mild hyperthyroidism Then, ↑TSH/↓FT4. (++) TPOAb and TgAb Biopsy: inflammatory infiltrate + fibrosis + necrosis	L-T4 replacement therapy
Riedel	Fibrous, IgG4		Insidious compressive local symptoms Fibrosis in other extrathyroidal locations No signs of systemic inflammation Hypothyroidism	Biopsy: fibrosis	Glucocorticoids in the early phase Surgery for compressive symptoms and signs

↑ elevated; ↓: decreased; (+): positive; (-): negative.

ESR, Erythrocyte sedimentation rate; *WBC*, white blood cell; *CRP*, C-reactive protein; *TSH*, thyroid-stimulating hormone; *FT4*, free T4; *TPOAb*, antithyroperoxidase antibodies; *TgAb*, antithyroglobulin antibodies; *FNA*, fine-needle aspiration; *NSAID*, nonsteroidal antiinflammatory drugs; *RAIU*, radioactive iodine uptake; *L-T4*, levothyroxine.

Etiopathogenesis and Physiopathologic Mechanisms in Autoimmune Thyroid Disease

Autoimmune Abnormalities. The human immune system is comprised of billions of B and T lymphocytes in relatively equal proportions. B lymphocytes (immunoglobulin-producing cells) develop from precursor cells in fetal liver and bone marrow and are found in all lymphoid organs and in the bloodstream. They exhibit antigen-specific receptors on their surface membranes, and they generate and secrete specific antibodies following antigenic stimulation. B cells are continuously recirculating between the blood and lymphoid tissue, thus maximizing the chances of recognizing antigen.

T cells also develop from precursor cells in fetal liver and bone marrow and migrate to the thymus. T cell differentiation then initiates in the thymus in response to exposure to specific antigens and subsequent production of cytokines. In normal conditions, selection of nonautoreactive cells occurs by central immune tolerance mechanisms in the thymus itself. These naïve differentiated T cells are released from the thymus into peripheral lymphoid tissue, where they will await specific signals to further mature in response to antigens, costimulators, and cytokines. This differentiation implies that each lymphocyte subtype will eventually secrete a battery of specific cytokines, and, thus, generate subsequent specific molecular reactions, apart from serving as a potential identifier of each individual subpopulation.

Selection processes throughout these maturations phases, for which multiple cellular and humoral mechanisms are necessary, lead to elimination of autoreactive cells. The main participants in these reactions, apart from B and T cells and their specific subtype populations, include multiple chemokines, growth factors, antigen-presenting cells (APCs), natural killer (NK) cells, membrane receptors, surface molecules, and major histocompatibility complex (MHC) molecules.[4,5]

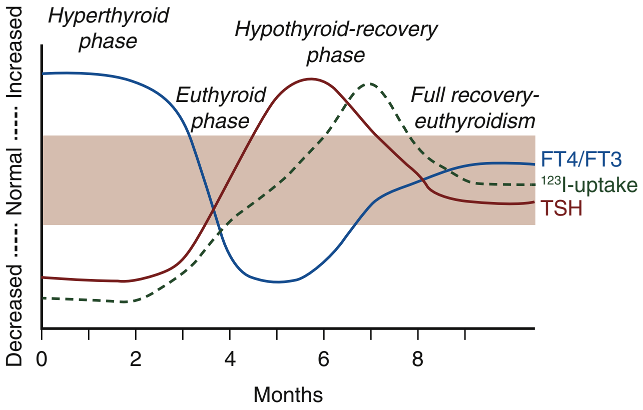

Fig. 73.1 **Graphical representation of the typical clinical course of various forms of thyroiditis, mainly painful subacute thyroiditis, painless postpartum thyroiditis, and painless sporadic thyroiditis.** Fluctuation is a frequent finding; patients with thyroiditis archetypally undergo an initial thyrotoxic phase, followed by hypothyroidism and eventual recovery. The horizontal axis represents time, and the vertical axis represents the quantity of thyroid-stimulating hormone *(green curve)*, FT4/FT3 *(orange curve),* and ^{123}I uptake *(dotted blue curve).* The green area represents the normal range of values. *TSH*, Thyroid-stimulating hormone.

However, some immune cells may escape these tolerance mechanisms, react to self antigens, and lead to proliferation of autoreactive clonal populations. Hypothesized explanations for this drift include genetic, environmental, and existential factors, which will be discussed in more detail later.[4,6,7] As a result, the concomitant action of B and T cells will generate autoantibodies and infiltrate the thyroid, reciprocally potentiating the autoimmune response with a mix of humoral and cellular mechanisms. Exosomes, microparticles, and miRNAs have also been associated with the onset and perpetuation of autoimmunity.[8-11] Some particularities occur in the specific setting of autoimmune thyroid disease (AITD).

KEY POINTS

- The typical clinical course of many forms of thyroiditis concerns an initial hyperthyroid thyrotoxic phase, followed by hypothyroidism and eventual recovery.

KEY POINTS

- The main auto-antibodies involved in thyroid autoimmune disease are anti-thyroid peroxidase (TPOAb) and anti-thyroglobulin (TgAb). Other antibodies such as anti-sodium/iodide symporter and anti-pendrin have been recently described.

Humoral Mechanisms. Detection of circulating thyroid autoantibodies has become the cornerstone for diagnosing AITD, in tandem with detection of autoreactive T cells. For clinical purposes, three main types of autoantibodies are considered, including those against TPOAb, those against thyroglobulin (TgAb), and those against the thyroid-stimulating hormone receptor (TSH-R–Ab); the latter is described in detail in the chapter on GD.[12]

Modern laboratory techniques allow a relatively precise quantification of these thyroid autoantibodies in serum, enabling a relatively specific diagnosis. Indeed, the more sensitive the assay, the more precise and antigen-specific it is. However, a considerable proportion of euthyroid individuals exhibit low titers of thyroid autoantibodies, meaning that the specificity of sensitive assays is reduced and making assessment of the total amount of thyroid autoantibodies more important. In this way, the higher the concentration of antibodies, the higher the specificity of the test. To optimally compare the results intra- and interindividually, there have been attempts to standardize assays, but each specific assay should be taken into account when considering them in the clinical follow-up.[13]

Both TPOAb and TgAb have been considered a result of thyroid damage, rather than the initial primary cause of thyroid destruction itself. In this regard, they are able to fix complement if they are of an appropriate IgG subclass, and thus facilitate complement-dependent antibody-mediated cytotoxicity, leading to thyroid tissue damage. Indeed, this cytotoxicity seems to lead to more damage to thyroid tissue than T cells and cytokine-mediated apoptosis.[13] In addition, antibody-mediated cytotoxicity also occurs through NK cells and macrophages. However, the resulting thyroid destruction may leave thyroglobulin (Tg) and thyroperoxidase (TPO) debris, perpetuating their significance as antigens in the subsequent development of thyroid autoantibodies. In fact, recent data show that thyroid antibodies may truly contribute to AITD outcome and chronicity.[14] TPOAb and TgAb are polyclonal IgG antibodies and are present in almost 100% of patients with AITD. In fact, almost all patients with HT have TPOAb. However, serum TPOAb and TgAb may be present in the general normal population, with a prevalence around 10% to 20% in relation to increasing age, with a clear difference between sexes (women are more prone to HT than men, with a 6:1 ratio), but with no clinically relevant thyroid disease. The significance of this finding may be related to an increased risk of future hypothyroidism, especially in the setting of a mildly elevated baseline thyroid-stimulating hormone (TSH).[15] For instance, subclinical autoimmune thyroiditis may occur after delivery in up to 50% of TPOAb-positive women. On the other hand, although few patients with AITD exhibit positivity for TgAb in the absence of TPOAb positivity, the opposite does not always occur. In this regard, because TPOAb levels are usually higher and bind with a higher affinity, they are usually considered the first choice if only one antibody is to be analyzed in screening for AITD.[13] All types of thyroid autoantibodies increase during AITD development if no treatment is established. Moreover, the process of thyroid hormone production itself may also contribute to the generation of immune-reactive C-terminal fragments, oxidative stress, presentation of epitopes by thyroid follicular cells, and further production of Tg and TPO autoimmune responsiveness.

Thyroid Peroxidase. TPO is expressed on the surface and cytoplasm of thyroid follicular cells and allows cell-surface antigen recognition, which may trigger complement-mediated cytotoxicity, as well as antibody-dependent cell-mediated cytotoxicity.[13] Binding to intracytoplasmic TPO suggests further access to this compartment, with potential immune consequences.

The role of TPO as a microsomal antigen was first described in 1985 by DeGroot's laboratory and Czarnocka et al. The interaction of human anti-TPO antisera and monoclonal antibodies denotes the presence of several B cell epitopes, with critical regions involving individual amino acids. In contrast, the search for T cell epitopes leading to AITD has yielded conflicting results, and only some sequences have been reported to exist in several patients.[12,13,15]

An interesting line of investigation is whether patients who develop hypothyroidism in the setting of autoimmunity differ in their epitope pattern from individuals with positivity to TPOAb but normal thyroid function. In fact, this could help predict which thyroid autoantibody-positive individuals will eventually become hypothyroid.[12,13,16]

A further possible role for TPOAb is its involvement in the controversial entity of Hashimoto's encephalopathy, as several reports have found that TPOAb binds to cultured astrocytes and may trigger some sort of autoimmune cross-reaction between the thyroid gland and the central nervous system.[17]

Thyroglobulin. Tg is a thyroid-synthesized protein that is the precursor of thyroid hormones. It behaves as one of the essential autoantigens in the pathogenesis of AITD through presenting several epitopes to B and T cells. For instance, a particular Tg T cell epitope, Tg2098, has been shown to bind strongly and specifically to the MHC class II disease-susceptibility HLA-DRβ-Arg74 molecule, which stimulates T cells and triggers the development of AITD.[18] In addition, the gene encoding Tg may confer susceptibility to autoimmune thyroiditis by coding for Tg variants of different immunogenicity.[19]

Other Antibodies. Several additional antibodies have been described in recent years. For instance, antibodies to the sodium/iodide symporter can potentially block its activity, although reports have described mixed results regarding its significance. Another reported autoantigen is pendrin, which is an apical protein involved in mediating iodine efflux from thyroid follicular cells into the lumen. In this case, pendrin antibodies have been found in around 80% of patients with AITD (mainly HT) when using immunoblotting techniques, but only in 10% when using radioligand binding assays. These antibodies have also been reported in up to 9% of healthy controls, thus further adding uncertainty to this finding. Thyroxine, triiodothyronine, and the insulin-like growth factor receptor have also been identified as potential autoantigens.[13] Furthermore, antibodies to other organs that are also susceptible to autoimmune disease, such as those directed against pancreatic islet cells, the adrenal cortex, the gastric mucosa, or the parathyroid, may be also detected with a higher frequency than in healthy controls, as will be discussed later in this chapter.

Cellular Mechanisms. Cellular immune mechanisms are closely related and cross-linked to humoral mechanisms in the development of AITD. In fact, once they are triggered, subsequent feedback circuits occur, with an eventual and reciprocal amplification and perpetuation of complex immune responses. Although cellular mechanisms have been traditionally attributed to HT, increasing evidence has proven that they are also related to the whole spectrum of AITD, including GD and Graves' orbitopathy.[5,20-23]

APCs, especially dendritic cells (DCs), are bone marrow-derived cells of both lymphoid and myeloid stem cell origin that populate all lymphoid organs, as well as almost all nonlymphoid tissues and organs. Human DCs are classified as immunogenic or tolerogenic, according to their functional role, depending on whether they activate autoreactive T cells or regulatory T cells (T regs), respectively. DCs are increased in thyroid-infiltrating cells in both GD and HT, where they can present immunogenic thyroid-related epitopes (e.g., Tg) to T cells. Moreover, an altered proportion and function of tolerogenic DCs has been suggested as an additional potential contributor to the pathogenesis of AITD.[5,24] Thyroid follicular cells may also act as APCs, favored by their ability to secrete specific recruitment chemokines, and in the setting of a highly vascularized endocrine gland.[25]

B cells are mainly involved in humoral immune mechanisms, so their role has traditionally been attributed to the production of TRAb and subsequent onset of GD. But in this same manner, B cells are also responsible for the production of TPOAb and TgAb by means of the usual mechanisms: they recognize soluble antigens through their specific cell membrane immunoglobulin receptors, synthesize antibodies, and act as APCs to CD4+ cells. B cell activation is further promoted by T helper (Th) cells, contributing to the spread and diversification of polyclonality. In addition, B cells take part in the thyroid lymphocytic infiltrate, where they also exert their role as antibody producers, enhancing the relevance of the thyroid itself in perpetuating AITD.

T cells also form part of the thyroid inflammatory infiltrate in AITD, and they are subclassified in two main subtypes according to their predominant role: cytotoxic T cells (Tc), mainly CD8+, and Th cells, mainly CD4+, which interact with other surrounding cells and secrete specific cytokines. Further differentiation of CD4+ naïve T cells leads to the emergence of specific subsets, namely Th1, Th2, Th17, and T reg.[5]

The Th1 response has been the one traditionally ascribed to HT. In this case, Th1 cells emerge following stimulation by IL-12, IFN-γ, and T-bet, and synthesize IL-1, IL-2, IFN-γ, and TGF-β, through activation of the CCR5 and CXCR3 receptors. This inflammatory infiltrate, together with macrophages and other subsets of T cells, will eventually lead to thyroiditis and destruction of the thyroid gland. On the other hand, Th2 cells, which emerge because of IL-4 stimulation, synthesize IL-4, IL-5, IL-6, IL-10, and IL-13 and mediate a predominantly humoral response. In fact, they interact with B and plasma cells and allow production of antibodies. In this regard, recent evidence proved that this occurred not only in GD, as it was classically described, but also in HT, where TPOAb and TgAb contribute to thyroid destruction by means of antibody-dependent cell-mediated cytotoxicity and complement activation.[5,21,23]

T regs are regulatory CD4+ CD25+ Foxp3+ cells. They recognize self antigens, proliferate only to a limited extent, and inhibit activation of, proliferation of, and cytokine synthesis by other lymphocytes. They also complete their regulatory role by interacting in cell–cell mechanisms and producing antiinflammatory cytokines, mainly TGF-β, IL-10, and IL-35. If T reg cells escape their own immunoregulatory processes, and autoreactive T reg cells prevail, with defects in their number and/or function, loss of self-tolerance and potentiation of AITD may occur. In this regard, for instance, Foxp3 mutations and defects in the immunosuppressive effect of CD69 have been recently reported as reasons for the inability to downmodulate the autoimmune response and tissue damage.[26,27]

Th17 cells derive from Th stimulation by IL-β, RORC2, and STAT3. They predominantly synthesize IL-17A, IL-17F, IL-21, IL-22, TNF-α, and IL-β, and contribute to the proinflammatory environment. If Th17 cells further undergo exposure to specific antigens, two potential pathways can originate. In this regard, in the setting of IL-23, pathogenic proinflammatory Th17 cells will arise that secrete IFN-γ and granulocyte-macrophage colony-stimulating factor; on the other hand, when TGF-β prevails, differentiation to nonpathogenic Th17 cells, which are involved in mechanisms against different extracellular bacteria and fungi and tissue repair, will occur.[5,28,29]

Another issue that heightens the complex interrelationship between cellular mechanisms is cross-regulation of Th1, Th17, and T reg cells, which subsequently promotes tissue damage in autoimmune conditions.[5,30] For instance, Th17 cells may differentiate into Th1-like cells or to Fop3+ Treg cells, but Treg cells may also evolve to Th17, and a mixed Th17/T reg phenotype has even been observed.[5,31-33]

This complexity in T cell regulation of has not been fully clarified yet in the particular setting of AITD. Recent findings point to a predominance of Th17 cells and their derived cytokines in peripheral blood and in the thyroid gland of patients with AITD, mainly those with HT,[25] which presumably would be of the pathogenic lineage and prevail over T reg cells. Moreover, circulating microvesicles, several Th17-related cytokines, leptin, and galectins, amongst others, could also contribute to a higher promotion of these proinflammatory Th7 cells, whilst the role of thyroid hormones still needs further investigation.[5,8,24,34]

Chemokines and Cytokines. Patients with HT seem to exhibit higher circulating levels of IL-6, IL-15, and IL-22, whereas IL-17 and IL-22 can be both found in thyroid tissue.

IL-17 is a proinflammatory cytokine, and numerous cells express IL-17R, suggesting that IL-17 serves as a bridge between the innate and adaptive immune responses. In fact, IL-17 stimulates NF-κB and mitogen-activated protein kinase pathways, and this induces proinflammatory cytokines, recruitment of neutrophils and macrophages at inflammation sites, and T cell proliferation. In addition, it will also trigger the upregulation of further proinflammatory cytokines, perpetuating the induction and exacerbation of the process. In this regard, IL-17 has been ascribed a significant role in AITD, mainly in HT and severe GD.[25]

IL-23 is produced by activated macrophages and DCs and has been described as a key Th17-polarizing mediator. As such, it can promote the proliferation of memory T cells and further production of IFN-γ. In addition, it helps maintain an adequate microenvironment for Th17 by mediating upregulation of IL-17.[34,35]

Apoptosis. Ultimately, autoimmune thyroiditis, and especially HT, is characterized by apoptosis of thyroid cells, eventually leading to follicular destruction, and not so much by hyperplasia. Depending on the degree of thyroid destruction, there may be certain residual thyroid function, and thus the clinical impact on thyroid hormones may be variable.

Both TPOAb and TgAb can bind to the complement system and trigger cytotoxic mechanisms, while B and T cells also infiltrate the thyroid gland. In fact, Tc cells, which are mainly CD8+, mediate direct apoptosis and destruction of thyroid follicular cells through activation of the CD95 membrane receptor (Fas–FasL). The reason for which thyroid cells express Fas may be related to T cell blastic transformation after exposure to thyroid antigens and subsequent release of cytokines. In this regard, cytokines have demonstrated to play a very relevant role on the onset of thyroid destruction, in the setting of an inflammatory infiltrate. Additionally, humoral mechanisms will come together in this complex autoimmune loop to perpetuate the autoimmune process.[5,34,35]

Clinical Relevance: Viewing Autoimmunity From a Perspective of Trying to Understand Autoimmune Thyroid Disease. Immune mechanisms involved in the onset and development of AITD are truly complex. Although there is currently a large amount of evidence regarding this condition, there is probably still much to be discovered and integrated, including other potential cell subsets, mediators, and functions. Fig. 73.2 represents a simplified summary of the currently known major components in an attempt to graphically show how

Fig. 73.2 Schematic representation of cellular and humoral mechanisms involved in thyroid autoimmunity. Antigen presenting cells (*APCs*) in thyroid tissue and peripheral blood may recognize self antigens and present them to T cells (decreased self-tolerance), leading to specific T helper (Th) cell differentiation according to targeted cytokine production. Increased Th1 activity will mediate cytotoxicity and infiltration (mainly through IL-12 and IFN-γ). Increased Th2 activity (mainly mediated through IL-4) will lead to increased autoantibody production. Increased Th17 activity (mediated through IL-17) will lead to increased differentiation of pathogenic Th17 cells and subsequent inflammation. Decreased T regulatory (T reg) activity jeopardizes the immunosuppressive effect for other T effector cells. ↑, Increased; ↓, decreased. (Reproduced from Ramos-Levi AM, Marazuela M. cellular and immune mechanisms come together in AITD, as well as its clinical implications.

Environmental Factors. Exogenous environmental factors may contribute to the development of AITD. It is interesting to note that some factors may have opposite effects on the development of the different types of AITD (GD or HT) and, furthermore, that some factors may protect against, rather than promote, the onset of AITD.[14,36] The most frequently associated factors include smoking, alcohol, selenium,[37-39] microparticles,[8] vitamin D,[39-44] iodine and any form of iodine supplementation, including drugs like amiodarone or lithium,[39,45] stress,[6,13,14,36] infections (although without identification of a specific, unequivocal pathogen),[6,13,14,36] drugs and other toxic substances, and radiation.[6,13,14,34,36] The influence and relationship of these factors in AITD are described in the chapter on GD.

Genetic Background and Susceptibility Genes for Thyroid Autoimmunity. Epidemiological evidence of familial clustering of AITD foresees a genetic susceptibility. In fact, up to 30% of siblings of patients with AITD eventually develop the condition, there is an increased sibling risk ratio for AITD (up to 17), and there is an increased prevalence of thyroid autoantibodies (up to 50%) in family members of affected individuals.[46,47] Moreover, studies in twins showed an increased concordance rate in monozygotic twins versus dizygotic twins (0.3–0.6 vs. 0.0–0.1).[48,49] Additionally, a recent National Health and Nutritional Examination Surveys study highlighted racial variations in the prevalence of AITD, suggesting potential genetic differences and the role of genetic susceptibility in the etiology of GD and HT.[50,51]

Several genes have been identified as being significantly associated with AITD and the presence of thyroid antibodies.[34,46,52]

Case-control studies, tag single nucleotide polymorphism screening, genome-wide association studies, and immunochip studies have identified some genes potentially involved in the development of AITD (Table 73.3). It is worth noting that the majority of these genes are known are immunoregulatory genes involved in T cell function, strongly suggesting the relevance of these cells in the onset and perpetuation of AITD. In this regard, certain polymorphisms may uniquely predispose to GD, HT, or both, whereas others are not thyroid-specific and increase the likelihood of autoimmunity in general.[34,46]

Existential Factors. Age, sex, parity, breastfeeding, and X-chromosome inactivation have been linked to AITD,[13,14,34,36] as is explained in the chapter on GD. Additionally, some studies have observed an association between the month of birth and the future potential development of AITD, or even that a specific month of the year could be associated to a higher incidence of these diseases, in line with observations in type 1 diabetes mellitus (T1DM) and multiple sclerosis.[53] Implicated seasonal factors include viral epidemics, ultraviolet radiation, vitamin D, and country latitude.

KEY POINTS

- Exogenous environmental factors and a genetic susceptibility background contribute to the development of thyroid autoimmune disease.

Stages in the Development of Autoimmune Thyroid Disease

The information provided earlier demonstrates the vast complexity of AITD pathogenesis. Autoimmune abnormalities and environmental, genetic, and existential factors play a significant role in thyroid disturbances,[7] as represented in Fig. 73.3. In addition, Fig. 73.4 attempts to summarize the series of events occurring during the different stages of the development of AITD. Perpetuation of these mechanisms will eventually lead to clinically evident chronic thyroiditis.

KEY POINTS

- The autoimmune process in Hashimoto's thyroiditis will eventually lead to thyroid dysfunction

TABLE 73.3 **Susceptibility Genes for Autoimmune Disease**

Method of Identification	Gene	Function
Case-control studies and tag single nucleotide polymorphism screening	*PTPN22*	T cell signal transduction through interaction with molecules critical for T cell receptor signaling
	CTLA4	Inhibition of T cell signaling
	Histocompatibility antigen (*HLA*) class II molecules	Presentation of exogenous antigens for recognition by CD4+ T helper cells. T cell activation
	IL2RA	Encodes CD25, which is expressed on T regulatory cells and downregulates T cell activity (peripheral tolerance)
Case-control studies and confirmation by genome-wide association studies	*FCRL3*	Expressed during B cell maturation to regulate their function in both ways
	HLA class I molecules	Presentation of endogenous antigens (e.g., viral) for recognition by CD8+T cells. T cell activation
	TSHR	Receptor for thyroid-stimulating hormone, the primary autoantigenic target in Graves' disease
Genome-wide association studies and immunochip	*GDCG4p14*	Expressed in CD4+ T helper and CD8+ T cells
	BACH2	Expressed during B cell maturation, controls B cell development and antibody production
	RNASET2	Expressed in CD4+ T helper and CD8+ T cells
	FOXE1	Involved in thyroid gland morphogenesis. Binds response elements in the thyroglobulin and thyroid peroxidase gene promoters
	FOXP3	Both transcriptional repressor and activator for primarily immunological genes (e.g., inhibits IL-2 and IFN, or activates CD25)
		Crucial regulator of regulatory T cells differentiation and function
	Others yet to be described	Unknown functions

Fig. 73.3 Schematic representation of the mechanisms involved in the onset of autoimmunity, and their complex interrelationship. Certain genes may increase the susceptibility to autoimmune disease, for instance, *PTPN22, CTLA4, HLA, ILR2A, FCRL3, TSHR, GDG4014, BACH2, RNASET2, FOXE1, FOXP3, CD40, FCRL3,* and *IL2RA*. Additional endogenous factors, such as age, sex, skewed X-chromosome inactivation, pregnancy/parity and seasonality, and exogenous factors, including smoking, alcohol, selenium, vitamin D, iodine status, infections, toxic substances and drugs, microparticles, stress, and radiation, may contribute to dysregulation of the immune system and onset and perpetuation of autoimmunity.

Natural History and Clinical Features

Given the progressive nature of autoimmune disorders, patients with early-stage HT are usually euthyroid and with no goiter, or a very small one. In this regard, the presence of thyroid autoantibodies would be the only detectable evidence of autoimmune thyroiditis, with pathological thyroiditis being only subclinical. In fact, postmortem studies in individuals with no overt thyroid disease have revealed that positivity for thyroid antibodies, especially TPOAb, significantly correlates with the presence of thyroid lymphocytic infiltration. Progressive development of the disease usually leads to a more firm and diffuse goiter of variable size, a stage in which patients are usually referred as "having chronic autoimmune thyroiditis."[2]

Goiter may be an incidental finding at physical examination, but some patients may experience local discomfort. Neck palpation usually reveals a firm consistency, but sometimes it may also give the impression of being hard, requiring differential diagnosis with malignancy. In any case, compressive symptoms and pain are rare in HT, allowing its differentiation from Riedel's thyroiditis and SAT, respectively, but if a thyroid nodule is identified, further investigation must be performed to rule out the potential coexistence of thyroid cancer.[1,3]

At this time, findings regarding thyroid function may be variable, ranging from normal to a slight initial hyperthyroidism because of thyrotoxicosis and hormone liberation. When the disease progresses even more, goiter increases, histological fibrosis spreads, to the detriment of thyroid follicles, the gland atrophies, and hypothyroidism occurs, evolving into what is prototypically known as Hashimoto's disease in its clinical, final, lifelong phase (Fig. 73.5). Progression to overt hypothyroidism is reported to occur at an approximate rate of 5% per year; thus, aging in this setting may be associated with a higher rate of thyroid hypofunction. Some patients may seem to spontaneously return to euthyroidism after transient hypothyroidism; this may occur if thyroid destruction occurs at a slow pace, with a clinically evident goiter and high Tg levels, and in patients with subclinical autoimmune thyroiditis with an excessive iodine intake. In these cases, thyroid response following TSH administration may be used to evaluate the potential expected recovery of thyroid hormones, and reduction of iodine intake may reverse the problem. In some cases, patients may develop hyperthyroidism over time and after long-term replacement therapy with levothyroxine (L-T4), mainly owing to the existence of stimulating antibodies, or because of an acute aggravation of thyroid autoimmunity and subsequent destructive thyrotoxicosis. These latter episodes are then usually followed by transient hypothyroidism.[54]

HT is not as common in children, in whom thyroid antibodies are usually lower. In fact, the frequency of AITD in children and adolescents is low, and the disease is usually self-limited. Thus, when symptoms occur, they are generally mild, with small goiters, normal thyroid function or only subclinical dysfunction, and reversion to normality in up to half of cases.[55,56]

Relationship With Other Types of Thyroiditis and Graves' Disease

Clinical presentation of autoimmune thyroiditis as a whole may be variable; for instance, hypothyroidism may be a frequent finding that leads to diagnosis, but maintenance of euthyroidism for prolonged periods of time is not rare, as will be described later. Thus, considering the chronicity in the definition of HT, patients who suffer any of the

Fig. 73.4 **Flow diagram to illustrate the stages inthe autoimmune process leading to thyroid dysfunction.** Starting at a first basal state, in which there is a variable genetic susceptibility, with normal antigen exposure, no antibodies, and no symptoms, exogenous precipitating factors may initiate the autoimmune response and thyroid damage. The possibility of autocontrol and returning point exists, but perpetuation of the autoimmune response will lead to secondary disease, augmenting factors, disease progression, and clonal expansion. *TPO,* Thyroid peroxidase; *Tg,* thyroglobulin; *TSHR,* thyroid-stimulating hormone receptor; *Ab,* antibody; *Ag,* antigen; *Tc,* cytotoxic T cell; *NK,* natural killer cell; *Treg,* regulatory T cell; *Th,* T helper cell.

autoimmunity-related thyroidites have a higher risk of later developing HT. In fact, some authors have reported that silent thyroiditis behaves as the starting point of subsequent HT. Furthermore, individuals with adequately controlled HT may develop some sort of silent thyroiditis during their lifetime; for instance, young women with HT may develop postpartum thyroiditis, demonstrating the complex spectrum of forms of AITD.[1-3]

Patients with untreated GD sometimes progress to hypothyroidism because of autoimmune destruction, in a similar way to what occurs in other types of thyroiditis, but also because of thyroid receptor-blocking antibodies. In fact, around 10% of thyrotoxic GD patients have been found to have both stimulating and blocking TRAbs, resulting in a trend for hyperthyroidism when stimulating antibodies prevail but progression to hypothyroidism when blocking antibodies are dominant. Overall, patients' clinical features will depend on the balance between stimulating versus blocking antibodies, and between the destructive aspects of humoral and cellular immunity. However, once thyroid cells are destroyed and overtaken by fibrosis, stimulating factors will be ineffective, limiting the occurrence of hyperthyroidism. This becomes relevant in clinical practice because patients with HT on adequate replacement therapy are not exempt from developing hyperthyroidism because of GD if there is viable residual thyroid tissue that can be targeted by stimulating TRAbs.

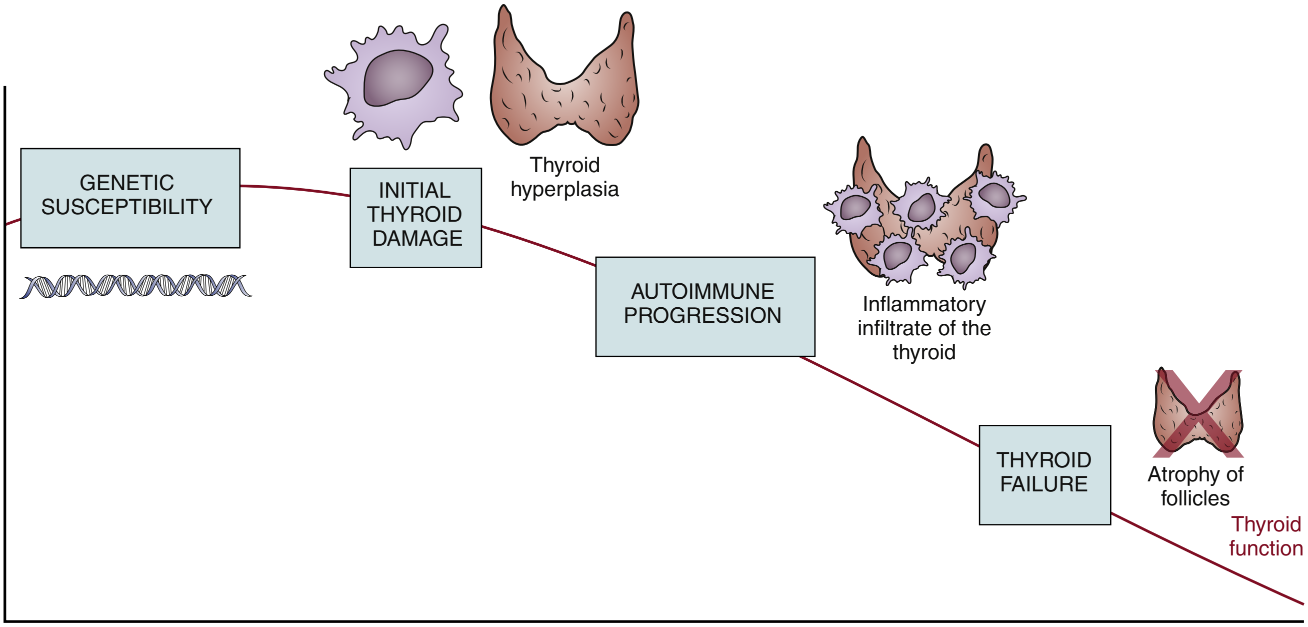
HT has sometimes been subclassified into Ig4 thyroiditis and non-IgG4 thyroiditis, although not without debate (see later). The controversy arises from the observations that some key histologic features of the IgG4 subtype may not be present, concomitant synchronous extrathyroidal involvement is frequently absent, and serum IgG4 is not always specifically directed against Tg. Thus, HT could also be regarded as a condition in which tissue and serum IgG4 may be detected, but with uncertainty regarding its significance.

Relationship With Other Autoimmune Diseases

AITD is associated with organ-specific and systemic autoimmune disease, including T1DM, autoimmune adrenalitis, autoimmune hypoparathyroidism, autoimmune hypophysitis, vitiligo, myasthenia gravis, thrombocytopenic purpura, alopecia, Sjögren syndrome, rheumatoid arthritis, systemic lupus erythematosus, and progressive systemic sclerosis. In addition, there is an increased prevalence of celiac disease in patients with HT.[57-60] These issues are extensively reviewed in the corresponding chapter.

KEY POINTS

- Autoimmune thyroid disease may be associated with organ-specific and systemic autoimmune disease, and to development of thyroid malignancy.



Natural history of Hashimoto's thyroiditis

Fig. 73.5 Schematic representation of the natural history of Hashimoto's thyroiditis. Certain individuals may exhibit a genetic susceptibility to thyroid damage owing to the combined action of endogenous and exogenous factors, leading to thyroid hyperplasia. Progression of autoimmunity leads to an inflammatory infiltrate of the thyroid, with subsequent eventual gland failure attributed to follicle atrophy. The curve represents thyroid function over the course of time. The thyroid diagrams represent the changes the gland exhibits.

HASHIMOTO'S THYROIDITIS AND THYROID MALIGNANCY

Epidemiological studies have reported an average coexistence rate between HT and papillary thyroid cancer (PTC) ranging from 5% to 85%.[61-63] This cooccurrence suggests an underlying immunological connection between both entities, as has been reported in several experimental studies. In line with this observation, the incidence of thyroid nodule malignancy is increased in the setting of positive autoimmunity and/or high TSH levels, in comparison with nonautoimmune nodular goiter. In addition, HT was more frequent in patients with PTC than in those with benign diseases.[64] Interestingly, however, HT has also been suggested to play a protective role against the progression of PTC.[62] In this regard, in a small metaanalysis, PTC patients with coexisting HT were found to have less aggressive clinicopathologic characteristics (i.e., lower rates of extrathyroidal extension and lymph node metastasis) and longer recurrence-free survival.[62] A further and more recent, larger metaanalysis, with a predefined subgroup analysis, proved the association of HT with better PTC outcomes, regardless of tumor size and regional iodine status.[65] Again, the underlying mechanism is not fully understood. A potential explanation concerns the increased expression of the RET/PTC-RAS-BRAF cascade in nonneoplastic follicular cells; thus, in HT, there may be overlap between these molecular mechanisms involved in early tumor development and inflammation.[66] In any case, the connection between HT and PTC may be used as a prognostic factor in the clinical setting of PTC.

Autoimmune thyroiditis is also associated with B cell lymphoma. In this regard, the similarity in the sequence of clonal bands between HT and thyroid lymphoma suggests that the latter may derive from the former in around 40% to 80% of cases.[67] This condition primarily affects females in their sixth decade or older, and diagnosis is frequently motivated by rapid enlargement of a neck mass in the setting of previously known HT being treated with hormone replacement therapy. Fine-needle biopsy is the key for diagnosis. Remission is achieved in the majority of cases with chemotherapy and radiotherapy.

KEY POINTS

- The hallmark for the diagnosis of Hashimoto's thyoiditis is presence of thyroid auto-antibodies, particularly TPOAb.

Diagnosis

Physical examination of patients with HT may reveal a firm, bumpy, symmetric, painless goiter as the initial clue for diagnosis. However, around 10% of patients with chronic autoimmune thyroiditis may exhibit an atrophic gland, presumably as a surrogate marker of thyroid failure in the final stages of HT.[1,2]

The presence of circulating thyroid antibodies, particularly TPOAb, is the hallmark of HT. In fact, 90% and 20% to 50% of HT patients exhibit high levels of TPOAb and TgAb, respectively.[1-3] In this regard, clinical observation of diffuse or nodular goiter and serologic tests with positive results for TPOAb and/or TgAb are usually enough for reaching a definite diagnosis of HT. A minority of patients, however, also have thyroid receptor-blocking and stimulating immunoglobulins. On the contrary, evaluation of thyroid hormones (TSH, FT4, and FT3) is helpful if hypothyroidism is evidenced, but it must be taken into account that a significant proportion of patients may exhibit only subclinical dysfunction. In fact, no differences in the titers of thyroid autoantibodies have been observed between euthyroid and hypothyroid HT patients. Thyroid antibodies may be detected in a nonnegligible 10% of individuals in the general population, without any other clinical sign or symptom of autoimmune thyroiditis. These people should

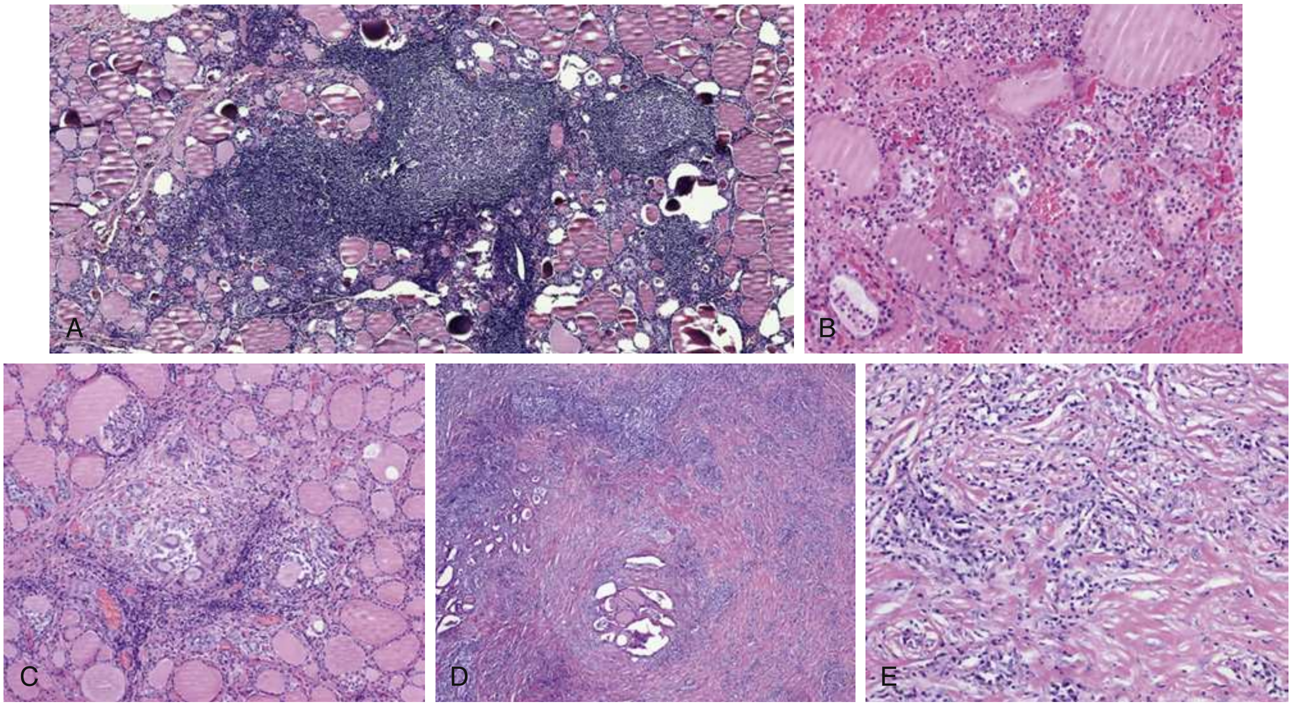


Fig. 73.6 Microscopy images of hematoxylin and eosin (H&E)-stained slides of Hashimoto's thyroiditis (H&E, 10×): Note the diffuse lymphoplasmacytic infiltration and lymphoid follicles with germinal center *(center of image, dyed in intense purple)* (**A**); acute thyroiditis (H&E, 20×): Note the increased presence of polymorphonuclear cells amongst the normal thyroid follicles (**B**); ,Subacute thyroiditis (H&E, 10×): Alteration and destruction of thyroid follicles, with interstitial edema, and with numerous histiocytes surrounding the remaining colloid, resembling giant cells, forming noncaseating granulomas with giant and inflammatory cells *(center of the image)* (**C**); Riedel's thyroiditis (H&E, 4× and 20×,): Extensive follicular and cell destruction, with scarring of the thyroid gland, and replacement of thyroid tissue by a dense fibrous tissue (**D**), and lymphohistiocytic inflammatory infiltrates causing obliteration of thyroid follicles (**E**). (Images kindly provided by Dr. Magdalena Adrados, from the Department of Pathology of Hospital Universitario La Princesa, Madrid, Spain.)

be viewed as having subclinical AITD, and monitoring of thyroid hormones is suggested.[12,13] In addition, primary hypothyroidism may be detected despite negative thyroid antibodies; in these cases, imaging techniques may aid in the differential diagnosis.

Given the potential hyperthyroidism that can occur in the initiation or follow-up of a patient with HT, differential diagnosis with GD, SAT, and toxic nodular goiter may be necessary. In this regard, duration of hyperthyroidism, evaluation of TRAb, serum T3/T4 ratio, ultrasonography, and radioactive iodine uptake (RAIU) may be helpful. Specifically, GD will exhibit longer and more severe hyperthyroidism than thyrotoxicosis, elevated TRAb titers, increased blood flow on ultrasonography, and increased RAIU (see chapter 71).

Thyroid ultrasonography is helpful when physical examination reveals abnormal thyroid palpation. Typical findings in a patient with HT comprise various degrees and heterogeneously distributed zones of parenchymal hypoechogenicity, with a thyroid volume that may range from normal-increased to frankly increased. In cases of atrophic thyroiditis, ultrasonography will show a reduced thyroid volume and a large number of hyperechoic fibrous streaks superimposed on a hypoechoic background. RAIU, however, will not be as helpful.[2]

Fine-needle aspiration cytology is required, following the same criteria for thyroid nodules, but it is sometimes performed in pseudonodular regions to confirm the diagnosis of chronic autoimmune thyroiditis and/or to rule out the presence of malignancy. In this latter clinical setting, findings will reveal lymphocytic infiltration, germinal centers, small follicles with oxyphilic cells, fibrosis, and atrophic areas (Fig. 73.6A).[2]

KEY POINTS

- First-choice treatment for Hashimoto's thyroiditis is levothyroxine replacement.
- There is no effective targeted treatment to reverse the chronic autoimmune process.

Treatment and Follow-Up

To date, there is no targeted effective treatment that reverses the occurrence or prevents the progression of chronic autoimmune thyroiditis. However, once overt hypothyroidism is present, replacement with L-T4 is the first choice of treatment for HT patients. L-T4 is also recommended in certain cases of subclinical hypothyroidism with positive autoantibodies, to anticipate progression to overt hypothyroidism and/or aid in the management of concomitant hyperlipidemia and atherosclerotic heart disease[68] (see chapter 74). In any case, the goal of treatment is achievement of euthyroidism with normal TSH values. Indeed, although no significant changes are observed in repeated fine-needle aspiration cytology after thyroid hormone normalization, a significant decrease in TPOAb and TgAb and reduction in thyroid volume may be noted after 1 year of treatment.[54] Daily replacement doses are usually calculated in accordance with body weight, around 1.2 to 2 mcg/kg/day. For young healthy adults, treatment can be started at full replacement doses; however, older patients or those with coexisting cardiovascular problems need lower starting doses (see chapter 74). Periodic monitoring of TSH values will allow a correct dose adjustment. Thyroid suppressive therapy will not prevent the occurrence of episodes of destructive thyroiditis, but, in repeated cases of painful events, ablative I-131 or surgical treatment may be an effective alternative. In fact, a recent randomized trial observed that total thyroidectomy was more effective than medical treatment in improving health-related quality of life and fatigue, possibly in the setting of concomitant elimination of serum TPOAb.[69]

There is some evidence for a potential role for micronutrients, namely iron, selenium, and vitamin D, in the treatment of HT.[70] Although the role of iodine in thyroid disease has been popularly discussed, most people with thyroid disturbances in iodine-replete areas have some form of AITD. Studies on the incidence of AITD are only available for a few developed countries, but it is true that AITD is more common in iodine-replete areas than in iodine-deficient ones, and even small increases in iodine intake are associated with an increased prevalence of thyroid autoimmunity.[1] With these data and recent evidence, high iodine supplementation is discouraged in HT, as it has not demonstrated any clear benefit and may even be associated with some potential harm. However, this should not preclude appropriate iodine supplementation during pregnancy.

Studies of the efficacy of selenium supplementation in HT patients have yielded conflicting results. On one hand, some metaanalyses confirmed a suppressive effect of selenium supplementation on serum TPOAb and TgAb levels.[71] However, another metaanalysis in the Cochrane library could not support or refute its efficacy.[72] There are several plausible explanations for these discrepant results, including heterogeneity of populations, differences in duration of HT and duration of the studies, the form in which selenium serum levels were measured, or the compound used as supplement. In this regard, selenium supplementation in the form of selenomethionine could be beneficial for HT patients with selenium deficiency and adequate iodine intake, but chronic intake of large quantities may have adverse health effects.

Regarding vitamin D, given the association of its deficiency with the pathogenesis of AITD, as well as the low cost and minimal side effects of vitamin D supplementation, screening for vitamin D deficiency and careful supplementation and monitoring may be recommended in HT.[73]

The association of HT with celiac disease advocates for a gluten-free diet to prevent the clinical course, progression, and complications potentially involved with HT and concomitant autoimmune diseases. However, this regime is not easy to maintain, and it is unclear whether it can truly prevent the onset of autoimmune diseases.[74]

KEY POINTS

- Hashimoto's encephalopathy is a rare autoimmune neuroendocrine syndrome that mimics various neurological and psychiatric disorders and responds to steroids.

Hashimoto's Encephalopathy

Recent clinical studies have suggested an individual susceptibility to psychopathology in patients with HT, regardless of thyroid function. The suggested mechanisms involve induction of neuroinflammation and alterations in serotonin signaling in the frontal cortex[75-78] and are different from the neurological manifestations that can appear in association with late-stage severe hypothyroidism. Moreover, vasculitis, autoantibodies targeting cells in the central nervous system, and dysregulation of hormones have also been postulated to be associated pathogenic mechanisms.

Hashimoto's encephalopathy (HE) is a rare neuroendocrine syndrome, perhaps an autoimmune disease of the brain, also known as steroid-reactive, or steroid-responsive, progressive or relapsing encephalopathy, that is associated with autoimmune thyroiditis. In fact, treatment with glucocorticoids seems to have a positive effect in the majority of cases. Despite its rarity, it is most common in middle-aged female patients.

Symptoms usually mimic a variety of neurological and psychiatric disorders, such as cognitive dysfunction, tremor, consciousness disturbances, transient aphasia, seizures, myoclonus, gait disorder, or even focal deficits mimicking stroke episodes, whereas psychotic symptoms may include paranoia, hallucinations, and mood disturbances.[79] Interestingly, the majority of patients are euthyroid or only slightly hypothyroid at the time of diagnosis, and up to one-third of patients may exhibit another concomitant autoimmune disease.

Diagnosis should be suspected in the setting of autoimmune thyroiditis with evident neurological or psychiatric symptoms, especially cerebellar disorders, seizures, and hallucinations, regardless of thyroid function. It requires exclusion of other more frequent entities. In this regard, brain imaging is nonspecific, and electroencephalogram may not be particularly informative, and only depict a regional slowdown of the frontal intermittent rhythmic delta activity, three-phase waves, sometimes epileptiform activity, and photoparoxysmal and photomyogenic phenomena. Elevated TPOAb is one of the criteria considered for diagnosis,[80] and there are some reports showing TPOAb in cerebrospinal fluid, presumably owing to intrathecal production.[17] Similar observations have been made regarding TgAb, but in lower proportions. In addition, some researchers consider that the increase in the level of antithyroid autoantibodies is proportional to the activity of the disease, and that their levels decrease after treatment with corticosteroids.[79] Proteins and pleocytosis are also frequent in cerebrospinal fluid evaluation. Antibody to alpha-enolase has been identified in some patients but is not specific to HE.

Treatment approaches may be similar to those used in any other autoimmune disease. For instance, short-term, high-dose glucocorticoids may be used, with subsequent tapering. Outcomes are generally favorable, but relapses may occur.

KEY POINTS

- Bacterial infections are responsible for the majority of acute, suppurative infectious thyroiditis. Its frequency is rather low. The clinical picture includes the sudden onset of local manifestations.

ACUTE/INFECTIOUS THYROIDITIS

Definition and Incidence

Acute, suppurative, infectious thyroiditis is usually related to bacterial infection (either gram-positive or gram-negative organisms, mainly *Staphylococcus* and *Streptococcus*), but fungal, mycobacterial, pneumocystic, or parasitic infections may also occur.[81,82] The normal thyroid gland is usually protected from infectious diseases owing to its encapsulation, high iodine content, rich blood supply, and lymphatic drainage[83]; thus, the overall frequency of this type of thyroiditis is usually low. However, in the presence of thyroid abnormalities, such as thyroid cancer, HT, multinodular goiter, or congenital anomalies, such as a pyriform sinus fistula adjacent to the larynx, or in patients with an altered and debilitated immune system, there may be a greater probability of developing opportunistic infections, via hematogenous spread.[84]

Clinical and Diagnostic Features

The main clinical manifestations of suppurative acute thyroiditis include the sudden onset of local manifestations such as dysphagia, dysphonia, anterior neck pain and erythema, and a tender thyroid mas, which may be unilateral and fluctuating, accompanied by general signs and symptoms of infection, such as fever, chills, and overall poor well-being. The onset of the clinical picture frequently occurs after an acute upper respiratory infection, which usually provides clinical guidance in addition to the clinical and analytical alterations. In the particular case of patients with acquired immune deficiency syndrome, opportunistic thyroid infections are more frequently insidious and chronic.[84]

Analytical data usually reveal findings consistent with a generalized infection, including elevation of leukocyte counts and erythrocyte sedimentation rates, while thyroid function tests are usually normal, although both thyrotoxicosis and hypothyroidism have also been reported.[83]

Regarding imaging findings, iodine uptake is usually "cold" (reduced) in suppurative areas. Thyroid ultrasound may aid in the differentiation between other types of thyroiditis if an abscess is identified. Fine-needle aspiration biopsy with gram staining and culture is the diagnostic test of choice to confirm the clinical suspicion if fluid collection with microbes on bacteriologic examination and culture are identified, together with an increased presence of polymorphonuclear cells amongst the normal thyroid follicles (Fig. 73.6B).[84]

Treatment and Follow-Up

Treatment of acute infectious thyroiditis relies on the proper administration of agent-directed antibiotics, preferably intravenously, as well as physical drainage of any abscess, if necessary. In cases of more chronic infections with bilateral disease, thyroid pain and tenderness may be less relevant, but may be accompanied by a reduced thyroid function, thus entailing the need for substitutive treatment with L-T4.

With a correct and prompt targeted therapy, prognosis is usually excellent, and recovery of the thyroid gland is usually complete. However, diagnostic and therapeutic delay may entail fatal consequences.

Postinfection follow-up depends on the specific pathogen, and initial thyroid function monitoring would be useful to rule out persistent alterations. Further radiologic studies, together with an otolaryngology consult and relevant head and neck examination, may be useful to identify fistulae or tracts contributing to the onset of infectious thyroid disease, to avoid recurrence.[84]

KEY POINTS

- Painful subacute De Quervain's thyroiditis is the main cause of thyroid pain. Its clinical features frequently involve the three-phase picture (inflammatory - recovery - stabilization).

SUBACUTE THYROIDITIS

Definition and Incidence

Painful de Quervain's SAT (nonsuppurative, giant-cell, granulomatous, pseudogranulomatous thyroiditis) is a self-limited thyroid inflammatory disorder that may occur in up to 5% of patients with clinical thyroid disease. Its incidence varies between 12 to 35 cases per 100,000/year, it is more frequent in young and middle-aged females, and decreases in frequency with increasing age.[1,85]

Several epidemiologic studies have described its higher incidence following an upper respiratory tract infection, typically 2 to 8 weeks before. An increased incidence has also been observed during the summer, suggesting seasonal incidence but also in relation to an increased peak incidence of enterovirus, coxsackievirus, mumps, measles, and adenovirus, amongst others, and thus a strong potential association with a viral cause, although viral inclusion bodies have not been observed in thyroid tissue.[85]

In fact, thyroid autoimmunity seems to have a less relevant role than in other forms of thyroiditis, even though a strong association with HLA-B35 has been described in many ethnic groups. In fact, the suggested hypothesis regarding this molecule concerns the identification of an antigen either derived from a subclinical viral infection itself or resulting from virus-induced host tissue damage. This antigen would bind to HLA-B35 molecules on macrophages and activate the cascade towards Tc cell differentiation and stimulation, which would cause tissue damage, because follicular cells have some structural similarities with the infection-derived antigen. As a result, a cytotoxic immune reaction directed to the thyroid gland occurs, but this is usually self-limited, unlike the perpetuating process occurring in HT.[34,86]

In any case, thyroid inflammation results in thyroid follicle damage, proteolysis of the accumulated Tg, and subsequent unrestrained release of thyroid hormones into the circulation, resulting a clinical and analytically evident hyperthyroidism. Normal thyroid function ceases during this thyroid alteration because of thyroid damage and to negative feedback of elevated T4 and T3 on TSH stimulation, halting thyroid hormone production. Thus, once the preformed hormone stores have been depleted, thyroid hormone levels may be restored, and, as inflammation wanes and thyroid follicular cells recover, thyroid hormone synthesis and secretion is restored. The velocity with which this process occurs may vary, making the transition from euthyroidism to hypothyroidism more or less relevant, as well as the degree of hypothyroidism, depending on how quickly the thyroid gland is able to regenerate and allow recovery of normal thyroid homeostasis.[1,85]

Clinical Features and Phases: Inflammatory, Recovery, Stabilization

SAT is the most common cause of thyroid pain. The clinical picture usually begins with a prodromal phase of generalized myalgia, pharyngitis, low-grade fever, and fatigue, resembling flulike symptoms. Patients then usually develop higher fever and severe neck pain and/or swelling; the latter may initially be confined to one lobe, but commonly spreads rapidly to involve the whole gland, a circumstance that is sometimes termed "creeping thyroiditis," and even radiate to the jaw and ears. Most patients also exhibit generalized symptoms to a variable degree and extent, including malaise, myalgia with or without arthralgia, mild feverishness, or high fever and anorexia. At this time, around half of patients may present hyperthyroid symptoms in relation to biochemical thyrotoxicosis because of thyroid hormone release form the inflamed gland. This onset of symptoms typically extends over 1 to 2 weeks and may continue with fluctuating intensity for 3 to 12 weeks, although it may last a year. Then, patients usually convert to a hypothyroid phase before returning to normal, as explained earlier.[1,85,87,88]

Diagnosis: Clinical, Laboratory, and Imaging Findings and Differential Diagnosis

The painful hyperthyroid phase may last for a couple of weeks or a few months. During this initial phase, thyroid palpation may reveal a smooth, firm enlargement, frequently accompanied by an exquisite tenderness. With time or treatment, thyroid tenderness wanes, and thyroid size generally returns to normal within several weeks or months.

Laboratory findings depend on the moment of evaluation. The typical course involves an initial phase of clinical and analytical hyperthyroidism, resulting from the initial release of thyroid hormone from the inflamed tissue during the thyrotoxic phase, with a suppressed TSH and elevation of total T4 and T3 levels (with a T3 ng/dL to T4 ug/dL ratio of typically <20). After a couple of weeks or months, a transient or permanent hypothyroid phase because of the lack of circulating thyroid hormones. Erythrocyte sedimentation rate is characteristically elevated, as well as C-reactive protein and Tg. In fact, plasma Tg may remain elevated long after all other evidence of the inflammatory process has dwindled. White blood cell count may be elevated in half of patients, so its normality does not exclude the diagnosis. Other reactants such as serum ferritin and IL-6 may be also increased during the inflammatory phase, reflecting the multisystemic nature of the process. In contrast, the antithyroid antibodies TPOAb and TgAb, as well as TRAb, may be absent or only present in low titers.

RAIU and scan typically reveals low uptake and poor visualization of the thyroid gland, as in all forms of thyroiditis. Thyroid ultrasound stereotypically shows a heterogeneously hypoechoic pattern and a suppressed vascular pattern. Application of newer technologies, such as sonoelastography, may provide further details regarding elasticity, which is decreased in SAT. In addition, T1 and T2 diffusion-weighted magnetic resonance imaging and (^{18}F)-fluorodeoxyglucose–positron emission tomography/computed tomography may aid in the differential diagnosis with GD.[87-88]

Diagnosis of SAT is mainly clinical. Differential diagnosis is usually required during the tender hyperthyroid phase, mainly with other forms of thyrotoxicosis, including GD, toxic nodular goiter, and acute thyroiditis, although basic clinical, analytical, and imaging data are generally enough to help guide the decision-making process (Table 73.2).

Pathology

Fine-needle aspiration reveals the presence of inflammatory cells, clusters of deteriorated follicular cells, and masses of colloid. A large-needle biopsy, or even a small, open surgical biopsy of the thyroid gland may be sometimes necessary to establish a definitive diagnosis. If histologic examination were always performed, a considerable inflammatory infiltrate would be easily identified, mainly composed of neutrophils, lymphocytes, and histiocytes, as well as the characteristic epithelioid granulomas, multinucleated giant cells, and follicular cells with intravacuolar granules. In addition, thyroid follicular cells would exhibit degeneration abnormalities, such as disruption, collapse, and necrosis (Fig. 73.6C). Although some fibrosis may also be evident, the eventual return of thyroid function to normal in the majority of cases is a surrogate for pathological thyroid recuperation.

Treatment and Follow-Up

In the majority of patients, SAT resolves spontaneously, but symptomatic treatment is usually prescribed to help accelerate the process. In fact, more than 90% of patients achieve complete resolution of pain and thyroid function.

In this regard, analgesic treatment with nonsteroidal antiinflammatory agents is frequently sufficient for pain relief; however, in cases with severe pain that do not respond to this initial step, a cycle of prednisone may be necessary, with daily doses of 20 to 40 mg, or equivalent, for 1 to 2 weeks, subsequently tapered down progressively over a period of around 6 weeks as symptoms wane. Occasionally, the clinical picture may be exacerbated when antiinflammatory therapy is decreased, requiring a return to a higher dose. The underlying pathogenic process cannot be altered with treatment, but the inflammatory response may be relatively tapered, allowing progression to a subclinical course.[1,87]

For thyrotoxic symptoms, beta-blocking agents are usually effective. Antithyroid drugs, on the contrary, are useless in the management of known, established SAT, as excess circulating thyroid hormone levels result from the liberation of preexisting hormones in the inflamed gland. Oral cholecystographic agents have sometimes been used to approach the hyperthyroid state when previous attempts are not effective. After this initial hyperthyroid phase of variable duration, L-T4 replacement therapy may be necessary, at least transiently, for more than low-grade hypothyroidism, but with a minimal dose to allow potential thyroid recovery. Long-term L-T4 therapy is more likely to be necessary in those patients who received corticosteroid therapy.[88]

The surgical approach is seldom required; in fact, despite the fact that it may be safe in expert hands, it is rarely used, and mainly in limited cases of persistent pain or refractory hyperthyroidism. Histologic examination of the inflamed thyroid glands has revealed an increased risk of associated papillary cancer.

Despite recovery from a clinical and analytical point of view, thyroid parenchyma may display residual scarring between thyroid follicles, resulting in residual patchy thyroid function. Indeed, around 10% of patients may suffer from residual permanent hypothyroidism and require replacement therapy, a circumstance that may occur more frequently with higher thyroid antibody levels.

KEY POINTS

- Silent thyroiditis is defined by painless thyroid enlargement, positive thyroid auto-antibodies and the three-phase archetypal stages of thyroid function test abnormalities. Diagnosis is often motivated by an incidental finding of altered thyroid hormone levels. Long-term follow-up is essential.

SILENT THYROIDITIS

Definition and Incidence

Given the somewhat similar pathological findings, painless thyroiditis has been considered a variant of HT, in the spectrum of AITD. In fact, many patients with silent thyroiditis exhibit high thyroid antibody titers and a frequent family background of AITD, and some even develop chronic autoimmune thyroiditis during follow-up, with subsequent thyroid function deficiency. In this regard, it seems that silent thyroiditis is caused by exacerbation of autoimmune thyroiditis. As with most thyroid disorders, its incidence is clearly higher in middle-aged women.[85]

Silent autoimmune thyroiditis may occur spontaneously or following pregnancy, with the latter being referred to as “postpartum thyroiditis” (see Chapter 75). It is usually defined by the combination of painless thyroid enlargement, positive antithyroid antibodies, and the typical course of thyroid function test abnormalities described for SAT (Fig. 73.1), over a 9 to 12 month course.

HLA-DR3 has been associated with the development of thyroid thyroiditis, although with a weaker relationship than in the case of HLA-B35 and SAT. Excess iodine intake and several drugs (lithium, amiodarone, tyrosin-kinase inhibitors, immune checkpoint inhibitors) and cytokines (IFN-α, IL-2) have been described as potential precipitating factors of an exacerbated immune response after some sort of underlying thyroid aberration.[89] In addition, painless thyroiditis has been associated with other immune-related circumstances, such as after glucocorticoid withdrawal, adrenalectomy for Cushing disease, lymphocytic hypophysitis, systemic lupus erythematosus, and immune thrombocytopenia, although a clear causal relationship has not been proven.

Clinical Features

Regardless of the precipitating factor determining thyroid inflammation and damage, rupture of thyroid follicles and Tg stores results in thyroid hormone release to circulation, with subsequent clinical hyperthyroidism. Then, around 5% to 20% of patients will have the archetypal sequence of hyperthyroidism, hypothyroidism, and recovery (Fig. 73.1), with the accompanying corresponding clinical symptoms, although to a milder extent. Some patients may even show additional repeated episodes over time throughout their whole life, unlike in SAT. Eventually, up to 30% of patients may develop chronic thyroiditis with permanent hypothyroidism, and some may even exhibit some degree of goiter.

Physical examination will not reveal a painful thyroid gland, but it may show some minimal diffuse enlargement.

KEY POINTS

- Radioactive iodine uptake (RAIU) is a mainstay for the differential diagnosis between thyroiditis and other causes of hyperthyroidism.

Diagnosis: Clinical, Laboratory, and Imaging Findings

Diagnosis is sometimes motivated by an incidental finding of altered levels of thyroid hormones. In such a circumstance, anamnesis may reveal that, in fact, some patients retrospectively exhibited a variable degree of symptoms that were overlooked at that time. Suspicion of painless thyroiditis should also be considered, for instance, in a middle-aged individual with short-term symptoms and no thyroid enlargement, as well as in a hyperthyroid patient who has been receiving therapy with immune checkpoint inhibitors, IFN-α, IL-2, or tyrosine-kinase inhibitors.

Laboratory findings concerning thyroid hormone levels are typically similar to those of SAT, with the hyperhypothyroidism sequence. In fact, many cases are diagnosed because of an altered TSH level, although it must be considered that changes in this parameter frequently run behind changes in free thyroid hormones. In any case, during the hyperthyroid phase, analytical perturbations may not be as intense as in GD, and only mild free hormone elevations with a relatively higher proportion of T4 than T3, or even only low serum TSH concentrations (subclinical hyperthyroidism) may be evident. During the hypothyroid phase, free hormone levels may be low, but also TSH levels, because of the time required for its recovery after the initial hyperthyroid phase. In later stages, TSH levels may be only mildly elevated, showing a state of subclinical hypothyroidism.

Acute inflammation reactant levels are not typically as elevated; in fact, the white blood cell count is usually normal, and the erythrocyte sedimentation rate and C-reactive protein levels are relatively normal or only mildly increased. However, and in a similar way to SAT, serum Tg levels are high, reflecting the proteolysis and secretion of preformed follicle stores, and this elevation may persist beyond thyroid recovery.

Antithyroid antibodies (TPOAb and TgAb), however, are typically elevated, as well as in postpartum thyroiditis, although not as much as in established HT, whilst TRAbs are usually absent or low, serving as a differential diagnosis with GD.

RAIU is low and is a mainstay for the differential diagnosis with other causes of hyperthyroidism. However, because recent exposure to large amounts of iodine may also cause low scintigraphy uptake, measurement of random urine iodine concentrations may sometimes be helpful to ensure that an elevated total body iodine content is not responsible for low thyroid uptake, to avoid misleading interpretations. Thyroid ultrasound is not usually required for the evaluation of patients with suspected thyroiditis, except for cases with concomitant goiter or palpable nodules; but, when performed, findings reveal the typical heterogeneous hypoechoic pattern with low vascularization, as observed in chronic autoimmune thyroiditis.

Similarly, although fine-needle aspiration is not part of the diagnostic routine in these patients, if performed, evaluation will show lymphocytes and macrophages, normal thyroid epithelial cells, damaged thyroid follicles, and masses of colloid. Then, during recovery, there would still be evidence of lymphocytic infiltration and maybe even some fibrosis, but more normalized thyroid follicles. In this way, the main differential characteristic from HT is that there would be a greater amount of damaged follicles, fewer lymphocytes and germinal centers, and less fibrosis.[1,85]

Once again, the differential diagnosis is usually required during the tender hyperthyroid phase, with other forms of thyrotoxicosis, and also with other causes of low RAIU thyrotoxicosis, such as iatrogenic or factitious thyrotoxicosis, ectopic thyroid hormone production, or Jod-Basedow effect because of iodine contamination (Table 73.2).

Treatment

Studies that evaluate the most optimal specific treatment for painless thyroiditis are somewhat scarce and are based on observational data and clinical experience. Thus, many patients can go without specific treatment during the different phases of thyroid dysfunction, given its frequent mild and transient signs. When a symptomatic approach is required, beta-blockers will serve to alleviate the hyperthyroid state or, in rare cases, glucocorticoid therapy may be necessary if thyroid function is severely altered. Antithyroid drugs, however, will not be useful, nor will radioactive iodine, because hyperthyroidism is not caused by increased thyroid hormone synthesis, as explained earlier.

Thyroid function should be frequently monitored, for example every 4 to 8 weeks, to anticipate the evolution to subsequent phases and eventual hypothyroidism. In the event of significant symptoms of hypothyroidism or significantly elevated levels of TSH (for example, >10 uU/mL), L-T4 replacement therapy may be useful. However, a trial of withdrawing this replacement therapy could be attempted after 3 to 6 months to evaluate potential thyroid gland recovery. In this regard, L-T4 dosage could be halved, and thyroid function tests reevaluated after 4 to 6 weeks; if TSH levels rise again, the previous dosage should be resumed, but if TSH levels remain normal, a further reduction could be probably attempted.[1,54,85]

Patients should be followed-up regarding thyroid function during the long-term, because of the possibility of recurrence and because of the potential advent of permanent hypothyroidism.

KEY POINTS

- Riedel's thyroiditis is a rare form of thyroiditis characterized by insidious and progressive fibrosis of the thyroid and adjacent structures. Clinical features include a hard and petrous enlargement of the gland and hypothyroidism.

RIEDEL'S THYROIDITIS

Definition and Incidence

Riedel's thyroiditis is a spectacular, although exceedingly rare, form of chronic fibrous thyroiditis that may occur in middle-aged women.

Etiology

The etiology of Riedel's thyroiditis has not been fully elucidated. In fact, there has long been controversy over whether it is a primary inflammatory disorder in the spectrum of advanced HT, or a local manifestation of a systemic fibrosing disease. In this regard, other fibrosing lesions, such as mediastinal fibrosis, retroperitoneal fibrosis, sclerosing cholangitis, and pseudotumor of the orbit, have been described to be also involved in this "multifocal idiopathic fibroesclerosis" systemic process.[90,91] Histopathologic examination reveals the presence of eosinophils, suggesting the role of an underlying autoimmune response to the fibrous tissue. In addition, a potential association with IgG4-related systemic disease has been hypothesized, given the observation of numerous IgG4+ plasma cells by immunohistochemistry[90] (see later).

Clinical Features

The main characteristic of this type of thyroiditis is fibrosis, which may occur in the thyroid gland itself and in adjacent structures. The thyroid gland is initially normal in size but may be considerably enlarged. Chronic inflamed fibrous tissue in the thyroid itself, and also in the adjacent skeletal muscle, nerves, blood vessels, trachea, and other distant organs, are typical findings. Indeed, involvement of the thyroid could even be regarded as part of the alteration of soft tissues in the neck, in the setting of the previously mentioned generalized fibrous state.[91,92]

The onset of symptoms is usually insidious; thyroid morphological disturbances may remain relatively stable for many years, but may slowly evolve to the onset of hypothyroidism in 25% to 30% of cases. In any case, symptoms are mainly related to compression of adjacent structures, such as the trachea, the esophagus, or the recurrent laryngeal nerve. In this regard, dyspnea, hoarseness, cough, and dysphagia may be frequent findings, and if there is enough pressure on both recurrent laryngeal nerves, there may even be stridor. Concomitantly, patients can frequently experience feelings of suffocation and local neck heaviness. If local fibrosis extends to the parathyroid glands, biochemical or even clinical hypoparathyroidism may develop. However, signs and symptoms of systemic inflammation do not occur, so patients do not show an increase in body temperature or pulse.

Physical examination reveals a remarkably distinctive characteristic: the hard and petrous consistency of the thyroid gland, which is usually enlarged, either in a symmetric or asymmetric way. This petrous consistency and invasion of surrounding structures may occur to such an extent that malignancy is the initial suspicion; however, in Riedel's thyroiditis, the absence of enlarged peripheral lymph nodes helps in the differential diagnosis.[92,93]

Diagnosis: Laboratory and Imaging Findings

Thyroid function is usually preserved, but some patients may develop hypothyroidism, or even hypoparathyroidism, owing to excessive fibrosis and impairment of normal cell function. Thus, RAIU may be normal or low. Thyroid autoantibodies are seldom positive, but, if they are, they are usually less elevated than in HT.

Ultrasonography can also be useful to guide diagnostic suspicion. In this case, Riedel's thyroiditis exhibits a homogeneously hypoechoic pattern, while elastography shows significant stiffness. Computed tomography, may display hypodensity, and magnetic resonance imaging will exhibit hypointensity on T1-weighted and T2-weighted images. Regardless of fibrous invasion in nearby soft tissue, if extrathyroidal invasion and/or vascular encasement is observed, the diagnosis of Riedel's thyroiditis is strongly suggested. Positron emission tomography reveals metabolic activity in the thyroid gland and may be useful for identification of other extrathyroidal areas of fibrosis, especially in the follow-up of patients.

Pathology

The ultimate diagnosis comes from histologic examination. Dahlgren et al. proposed the following histologic criteria for Riedel's thyroiditis: (1) fibroinflammatory process involving all or a portion of the thyroid gland; (2) presence of fibrous extension beyond the thyroid capsule into adjacent anatomic structures; (3) infiltration of inflammatory cells without giant cells, lymphoid follicles, oncocytes, or granulomas; (4) evidence of occlusive phlebitis; and (5) absence of a neoplasm.[90] Hürthle cell metaplasia, extrathyroidal extension of fibrosis, and obliterative phlebitis can aid in the differential diagnosis with the fibrotic variant of HT (Fig. 73.6D and E).

Treatment

In the absence of treatment, Riedel's thyroiditis usually develops slowly and continuously, but stabilization or even spontaneous regression have also been reported. This insidious progression entails a frequent delay in its diagnosis, with time lapses from the onset of observable signs of goiter that may range from 10 months to 2 years.

Surgical treatment may be hazardous and prone to complications, so it is not usually the mainstay of management. In fact, it is mainly indicated in two clinical scenarios: 1) to exclude malignancy; and 2) to relieve compression of adjacent structures, namely the trachea or the esophagus. Indeed, removal of the isthmus may alleviate symptoms if there is extensive invasive fibrosis, but neck dissection is not often performed, given the lack of resection planes and the risk of injuring adjacent structures. Replacement therapy with L-T4 is recommended when hypothyroidism develops, but has no effect on the pathophysiology or the progression of fibrosis.

To treat the underlying cause, immunosuppressive treatment, such as several forms of chemotherapy, glucocorticoids, tamoxifen, or the combination of glucocorticoids and tamoxifen, have been attempted in some patients, but efficacy has been low, with only sporadic improvement in some cases.[91,93,94] Awareness of other extrathyroidal fibrosing manifestations is essential in the follow-up of these patients.

KEY POINTS

- Riedel's thyroiditis is a rare form of fibrous thyroiditis whose etiology has not been fully elucidated.
- Histopathologic examination in Riedel's thyroiditis reveals a fibroinflammatory process, fibrous extension beyond the thyroid capsule into adjacent anatomic structures, infiltration of inflammatory cells without giant cells, lymphoid follicles, oncocytes or granulomas, phlebitis, and eosinophils.
- Malignancy is the main issue in the differential diagnosis of fibrous thyroiditis.
- A potential association of Riedel's thyroiditis with IgG4-related systemic disease has been hypothesized.
- IgG4 thyroiditis is characterized by an intense lymphoplasmacytic infiltration, dense interfollicular pattern of fibrosis, marked follicular cell degeneration, elevated serum IgG4, IgG4-positive plasma cells, and rapid progression to organ failure.

IgG4 THYROIDITIS

Definition, Incidence, and Relationships in the Setting of Other Subtypes of Thyroiditis

Since the first description of high serum IgG4 levels in the context of autoimmune pancreatitis and the subsequent acknowledgment that extrapancreatic organs could also be affected, IgG4-related disease (IgG4-RD), a fibroinflammatory, immune-mediated, systemic condition, has been reported to potentially occur in any organ.[95,96] Thus, the 2012 consensus guideline[97] proposed the term IgG4-RD to unify the terminology for the spectrum of these disorders (Table 73.4).

The observations that hypothyroidism and positive titers of TPOAb and TgAb are highly frequent in patients with autoimmune pancreatitis, and that the thyroid is one of the most commonly affected organs in autoimmune diseases, pointed to a potential link between IgG4-RD and the thyroid itself. In this regard, we now consider that IgG4-thyroid diseases comprise some cases of HT, its fibrotic variant, Riedel's thyroiditis, and even some peculiar cases of GD.

IgG4 thyroiditis is characterized by intense lymphoplasmacytic infiltration, a dense interfollicular pattern of fibrosis, and marked

TABLE 73.4 Diagnostic Criteria for IgG4-Related Disease (IgG4-RD)

1. Clinical examination	Clinical history, physical examination, imaging
2. Immunological examination	IgG4 in serum >135 mg/dL or elevated IgG4/IgG ratio; possibly accompanied by other laboratory tests, such as IgE, γ-globulin, or a complement
3. Histopathologic examination	Lymphoplasmocytic infiltration with storiform fibrosis and obliterative phlebitis, infiltration by IgG4-positive plasma cells (IgG4+/IgG+ >40%)
1 + 2 = possible IgG4-RD; 1 + 3 = probable IgG4-RD; 1 + 2 + 3 = definite IgG4-RD	

(Modified from Kottahachchi D, Topliss D. Immunoglobulin G4-related thyroid disease. *Eur Thyroid J.* 2016;5:231–239.)

follicular cell degeneration, in addition to other features common to IgG4-RD in other organs, such as elevated serum IgG4, mass-forming fibrosis with increased IgG4-positive plasma cells, and rapid progression to organ failure. Serum IgG4 presumably derives from IgG4+ plasma cells within the germinal center in the thyroid. In fact, circulating levels of IgG4 decrease after thyroidectomy.

The peculiar and rare fibrotic variant of HT, which was initially considered a late stage of HT, is actually considered a distinct clinicopathological entity consisting of severe compressive symptoms and firm malignant-like thyroid. It entails marked fibrotic replacement and typical inflammatory features in a lobular pattern, without extracapsular extension. The associated finding of increased IgG4+ cells and serum IgG4/IgG ratio suggests that this fibrotic variant, rather than HT as a whole, could actually be part of the spectrum of IgG4-RD.[91]

The role of IgG4 in GD is not straightforward, and the prevalence of IgG4-RD in patients with GD is presumably very low. Some particular characteristics include an older age at diagnosis, relative male predominance, a better response to antithyroid drugs, and a relatively higher rate of development of Graves' ophtalmopathy.[98,99] There is yet no strong evidence for the existence of IgG4 GD, but rather GD with a potential concomitant association with elevated IgG4.

IgG4-RD is a rather novel entity, entailing a potential underestimation of its real prevalence. For IgG4 thyroiditis, a heterogeneous prevalence has been reported, ranging from 5% to 27%. Several reasons may explain the discrepancies observed. First, there is the variability of histologic criteria and thresholds used to define increased IgG4-positive plasma cells and/or IgG4/IgG ratios across the different studies. In addition, the number of IgG4+ plasma cells depends on disease duration; specifically, these cells are characteristically increased at the onset of the disease but decrease in favor of fibrosis in more advanced stages. Furthermore, the low need for thyroidectomy in patients with thyroiditis may jeopardize the availability of a histologic definitive diagnosis. A rather surprising issue is its predominance in males, in contrast to the higher proportion of women affected in autoimmune diseases.[95,100,101]

KEY POINTS

- IgG4 thyroiditis usually entails the development of thyroid failure, tumefactive enlargement, compressive symptoms and suspicion of malignancy.

Clinical Aspects

IgG4-RD may mimic malignant disease owing to its subacute onset and the frequent development of tumefactive lesions. In the specific setting of the thyroid, it may seem similar to Riedel's thyroiditis, with a trend for more severe compressive symptoms and/or suspicion of malignancy, and subsequent relatively rapid progression to thyroid function failure owing to chronic autoimmune inflammation. The presence of pain may also serve as an indicator of the potential existence of IgG4 thyroiditis. In addition, patients may exhibit synchronous or metachronous lesions in extrathyroidal organs.[90]

Diagnosis

High levels of thyroid antibodies are frequently observed in patients with IgG4 thyroiditis. Ultrasonography usually reveals a hypoechogenic pattern.

Diagnosis relies on several key histologic features: dense lymphoplasmacytic infiltrates rich in IgG4 plasma cells, fibrosis with a storiform (irregularly whorled) pattern, obliterative phlebitis, and eosinophilic infiltration. Phlebitis without lumen obliteration and an increased number of eosinophils are considered minor nonspecific features.[97,102] IgG4 immunostaining is also important for the diagnosis.[102] Indeed, there should be positive IgG4 staining within the involved tissue, for example, thyroid or orbital tissue, for a definitive diagnosis of IgG4-induced thyroiditis or orbitopathy/exophthalmos. All other parameters are not specific or definitive for an accurate diagnosis. In this regard, the role of high circulating levels of IgG4 does not seem to be solely sufficient for a definitive diagnosis; in fact, other conditions, such as infections, connective tissue diseases, and immunodeficient states, may also exhibit high IgG4 levels, and multiple studies have reported conflicting results regarding its predictive sensitivity.

In spite of these uncertainties, today, the term "IgG4 thyroiditis" is used both when the histologic diagnosis (gold standard) is confirmed and when elevated serum IgG4 levels are present in a patient with thyroiditis, regardless of histologic confirmation, a circumstance that is rather frequent, because not many patients with thyroiditis require thyroidectomy as treatment. In an attempt to overcome this difficulty, levels of thyroid antigen–specific IgG4, rather than total serum IgG4, have been suggested to be more helpful for establishing a correct diagnosis.

Clinical, serological, and histological features need to be considered as a whole and collated with the proposed 2012 criteria to decide if a given case deserves the diagnosis of IgG4 thyroiditis.[100,101]

Treatment and Follow-Up

First-line therapy for IgG4-RD usually involves glucocorticoids, but azathioprine, mycophenolate mofetil, and methotrexate have also been commonly used as an alternative, or to maintain remission after glucocorticoid administration. In cases of recurrent or refractory disease, the anti-CD20 monoclonal antibody rituximab may be attempted with the aim of depleting B cells, as it is sometimes successful in treating Riedel's thyroiditis. Extensive and established fibrosis will encumber effectiveness of any of the attempted medical treatments, resulting in the probable need for surgery.

SUMMARY AND FUTURE DIRECTIONS

Thyroiditis comprise several forms of thyroid inflammation with variable repercussions for thyroid function. Their etiology, epidemiology, pathology, and clinical impact differ, and specific terminology has been developed accordingly. The most common forms of thyroiditis include HT, acute/infectious thyroiditis, de Quervain's SAT, silent thyroiditis, Riedel's thyroiditis, and IgG4 thyroiditis. Autoimmunity is the main etiopathogenic mechanism involved in thyroid disease, and its quintessential example is HT. Epidemiological data suggest an interaction between genetic susceptibility, existential factors, and exogenous environmental triggers in this breakdown of immune tolerance. Humoral and cellular immune mechanisms are closely related and cross-linked in AITD. Once they are triggered, they undergo subsequent feedback circuits, with combined amplification and inhibition processes, that reflect the complexity of these underlying pathways in the onset, development, and perpetuation of AITD, and that still deserve further investigation.

The various forms of thyroiditis may be interrelated, and studies have confirmed the association of AITD and other specific or systemic autoimmune disorders and thyroid malignancy. Long-term monitoring of AITD patients is required for adequate management. Further studies to clarify potential preventive or therapeutic approaches, beyond mere replacement therapy, will aid in identifying the optimal approach to treating AITD.

KEY POINTS

- Thyroid hormone is important for the function of all organ systems of the body; signs and symptoms of hypothyroidism are thus diverse.
- Hypothyroidism is most commonly caused by progressive autoimmune destruction of the thyroid gland. It most frequently occurs in women and older individuals and results in a lifelong requirement for thyroid hormone replacement.
- Although a constellation of symptoms characterize the hypothyroid state, the lack of pathognomonic symptoms may delay recognition of the need for testing for hypothyroidism.
- The laboratory hallmark of primary hypothyroidism is an elevated serum thyroid-stimulating hormone concentration.
- Treatment with synthetic thyroid hormone in the form of levothyroxine lowers serum thyroid-stimulating hormone concentrations to the normal range and reverses signs and symptoms of hypothyroidism in most patients.
- Optimization of levothyroxine treatment by facilitating adherence and avoiding overtreatment and undertreatment remains a challenge.
- Combination therapy with levothyroxine and liothyronine is being actively investigated as a potential therapy for patients in whom levothyroxine alone does not reverse their symptoms.
- Future advances may allow researchers and clinicians to prevent the development of autoimmune destruction of the thyroid gland or provide therapy in the form of directing progenitor cells to form functioning thyroid follicles *in vivo*.

BRIEF HISTORY

Thyroid diseases and their treatments have been documented in both written and pictorial form throughout history. Sixth-century Chinese scholars were apparently aware of the ability of seaweeds and thyroid glands from deer and sheep to treat goiters that occurred in mountainous region of the county,[1] the latter perhaps representing one of the earliest examples of "organotherapy." The facies depicted in artwork as diverse as the Adena pipe figurine from before the first century AD[2] and the Mona Lisa from the early 1500s[3] have been attributed to hypothyroidism. Although descriptions of myxedema existed, it was not until thyroidectomy was performed in Switzerland for goiter that resection of the thyroid was clearly linked to the subsequent development of myxedema.[4] Starting during the 1890s, various modes of thyroid hormone replacement have been attempted for treating hypothyroidism, including grafting of sheep thyroid glands in patients, intravenous injection of thyroid extract in dogs, and subcutaneous administration of sheep thyroid extract in patients.[5]

Oral administration of sheep thyroid extract was then used, with extraordinary improvement in the hypothyroid symptoms and signs of the patients, and also some descriptions of the toxicity of overreplacement. Desiccated thyroid extract (DTE) then became the standard of treatment for hypothyroidism for many years. Although thyroxine (T4) itself was isolated in 1914 and synthesized in 1927, it was not synthesized for commercial purposes until 1949. Identification, isolation and synthesis of triiodothyronine (T3) occurred from 1952 to 1953.

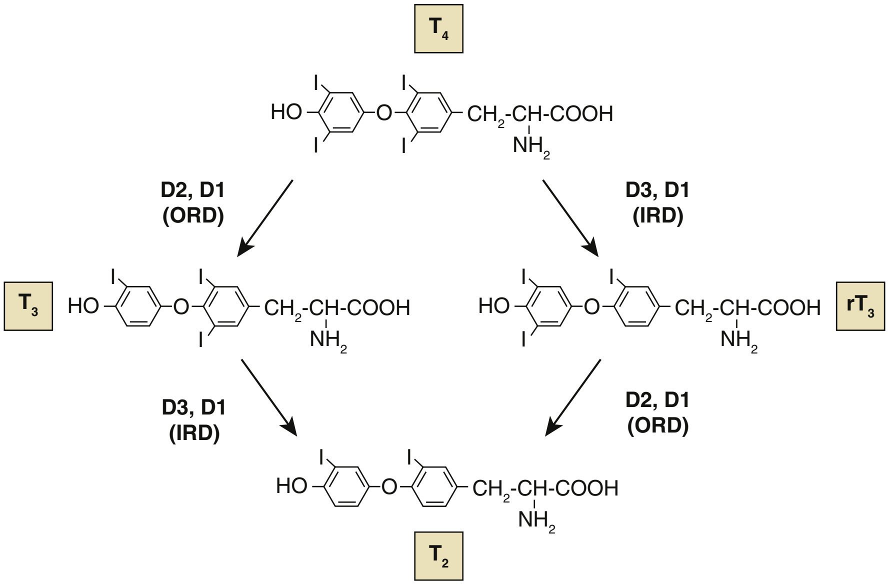

Fig. 74.1 **Deiodination of thyroid hormone isotopes.** (From van der Spek AH, Fliers E, Boelen A. The classic pathways of thyroid hormone metabolism. *Mol Cell Endocrinol*. 2017;458:29–38.)

Starting in the 1950s, levothyroxine (LT4) gradually replaced DTE as standard therapy. Although LT4 remains the most prescribed therapy for hypothyroidism, use of DTE continues, and interest in such therapy has been increasing in recent years.[6] This chapter discusses the diagnosis and treatment of hypothyroidism in adults.

HYPOTHALAMIC-PITUITARY-THYROID AXIS

The hypothalamic-pituitary-thyroid axis is a classic negative feedback loop involving four hormones. Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of thyroid-stimulating hormone (TSH) from the pituitary gland. TSH supports the synthetic machinery within the thyroid gland itself and stimulates the resorption of thyroglobulin from within the lumen of thyroid follicles. Both T4 and T3 are then released from the thyroid gland into the circulation in a ratio of approximately 14:1.[7] There is a reciprocal relationship between TSH and free T4 (FT4), such that, as the concentration of FT4 increases or decreases, the response is an exponential decrease or increase in TSH concentration. Thus, an inverse relationship is seen when TSH concentrations are plotted on a logarithmic scale versus FT4 concentrations on a linear scale. However, this relationship may be more complex than a simple linear one, with the slope of this relationship being affected by sex, age, genetics, and use of LT4. The relationship may actually be curvilinear, as opposed to linear, and each individual may have TSH-FT4 set points that differ from the population as a whole.[8] The development of primary hypothyroidism can thus be detected when the serum TSH concentration rises above the upper limit of its reference interval.

THYROID PHYSIOLOGY AND THYROID HORMONE ACTION

Dietary iodine in the form of iodide or iodate is absorbed by the gastrointestinal tract and distributed in the extracellular fluid. Circulating iodide is actively transported into the thyrocyte by the sodium-iodide symporter located within the basolateral membrane. Once iodide has translocated to the apical membrane, its efflux is mediated by three apical iodide channels. A hydrogen peroxide generation system is present at the apical surface of the thyrocyte. Molecules of the enzyme thyroid peroxidase, also present at the apical surface of the thyrocyte, are activated by hydrogen peroxide. Oxidized thyroid peroxidase can then in turn oxidize iodide. The reactive iodonium ion intermediate formed is then covalently bound to tyrosyl residues present in thyroglobulin to generate monoiodotyrosine and diiodotyrosine residues through a process known as organification. Thyroid peroxidase also catalyzes the coupling of the monoiodotyrosine and diiodotyrosine residues to generate T4 and T3 residues in thyroglobulin, which is secreted into the follicular lumen. As needed, thyroglobulin is then pinocytosed at the apical membrane, and T4 and T3 are secreted after proteolysis of thyroglobulin. Pharmacologic amounts of iodine inhibit iodide trapping, organification, and release of the thyroid hormones.

Thyroid hormones are necessary for the development and metabolic homeostasis of all the tissues and organ systems of the body. Depending on the various estimates, the intact thyroid gland produces approximately 85 to 100 mcg per day of T4 and 5 to 6.5 mcg per day of T3. This results in the direct thyroidal production of T4:T3 in the previously mentioned approximately 14:1 ratio. The deiodinase enzymes, which are selenoproteins, are involved in activating and deactivating thyroid hormones. Type 1 and 2 deiodinases convert the precursor T4 into T3, the active form of thyroid hormone, by outer ring deiodination, producing another 26.5 mcg of T3 daily. Type 3 deiodinase is responsible for converting T4 and T3 into their inactive forms of reverse T3 and 3,3′-diiodothyronine, respectively, via inner ring deiodination[9] (Fig. 74.1).

Although thyroid hormones are lipophilic, they nevertheless require specific thyroid hormone transporters to gain entry into cells. Three transporters from two transporter families have high specificity for thyroid hormones. These are monocarboxylate transporters 8 and 10 (MCT8 and MCT10) and organic anion transporting polypeptide 1C1.[10] Deiodinases and thyroid hormone transporters are differentially expressed in different tissues and are thus essential for the tissue-specific actions of thyroid hormones. Once it has gained entry into the nucleus of the target cell, the active ligand T3 binds to thyroid hormone receptors, which in turn bind, mainly as heterodimers with retinoid-X receptors, to thyroid hormone response elements in target genes[11] (Fig. 74.2).

Two genes, *THRA* and *THRB*, encode the thyroid hormone receptor proteins (TRα and TRβ), of which there are several splice products or isoforms. TRα1 is predominately expressed in brain, heart, and skeletal muscle. TRβ1 is widely expressed, while TRβ2 is mostly expressed in the brain, pituitary, retina, and inner ear, and TRβ3 is mostly expressed in kidney, liver, and lung. This differential expression of TRα and TRβ is also essential for the tissue-specific actions of thyroid hormones. Following the binding of the heterodimer complex to the thyroid hormone response element with in the target gene, there is ensuing RNA transcription and protein synthesis to generate the cellular response to thyroid hormone. Most genes are positively regulated by T3, although some are negatively regulated.[12]

EPIDEMIOLOGY

Throughout the world, the prevalence of hypothyroidism varies from 0.25% to 4.2%.[13] Prevalence rates differ in iodine-sufficient countries versus iodine-deficient countries. For example, in an iodine-deficient country (Denmark), the overall prevalence of overt hypothyroidism was 0.37%, compared with an overall prevalence of overt hypothyroidism in an iodine-sufficient area (Norway) of 0.7%. The incidence of hypothyroidism generally increases following introduction of iodine fortification programs. Prevalence rates also differ by sex and age, with more hypothyroidism in women and in older age groups. To illustrate the effect of sex, in the 1995 report of the 20-year follow-up analysis of the Whickham population the prevalence of hypothyroidism was 1.3% and 9.3% in men and women, respectively. To illustrate the effect of age, the prevalence of hypothyroidism ranges from 1% to 2% in some studies, compared with 7% in a study of individuals aged between 85 and 89 years. Cases of subclinical hypothyroidism (SCH) exceed those of overt hypothyroidism. For example, in a study using National Health and Nutrition Examination Survey III data the overall prevalence of hypothyroidism was 4.6%, with 0.3% being overt hypothyroidism and 4.3% being subclinical disease.[14] With respect to overt hypothyroidism, the prevalence in the general population depends on the definition used and population studied and ranges from 0.2% to 5.3% in Europe and from 0.3% to 3.7% in the United States.[13]

CLINICAL MANIFESTATIONS

The clinical manifestations of hypothyroidism are diverse and potentially emanate from the effects of thyroid hormone deficiency in any organ system of the body[15] (Table 74.1). Both signs and symptoms can occur across a wide spectrum of severity, ranging from subtle to profound.

Symptoms

The symptoms of hypothyroidism reflect the effect of low levels of thyroid hormone throughout the body. Symptoms may be mild and barely perceptible or can be severe. In addition, symptoms of hypothyroidism are nonspecific and can overlap with symptoms of nonthyroid origin. For example, weight gain can be associated with untreated hypothyroidism, but can also occur in euthyroid individuals. The same statement can be made concerning the presence of fatigue, constipation, memory problems, and dry skin. To provide some examples, in one study, dry skin was reported in 71% of those with hypothyroidism versus 54% of those who were euthyroid, muscle weakness was described in 21% of those with hypothyroidism versus 21% of those

TABLE 74.1 Symptoms and Signs of Hypothyroidism

	Presentation	Signs and Implications
General metabolism	Weight gain, cold intolerance, fatigue	Increase in body mass index, low metabolic rate, myxedema,[a] hypothermia[a]
Cardiovascular	Fatigue on exertion, shortness of breath	Dyslipidaemia, bradycardia, hypertension, endothelial dysfunction or increased intima media thickness,[a] diastolic dysfunction,[a] pericardial effusion,[a] hyperhomocysteinemia,[a] electrocardiogram changes[a]
Neurosensory	Hoarseness of voice, decreased taste, vision, or hearing	Neuropathy, cochlear dysfunction, decreased olfactory and gustatory sensitivity
Neurological and psychiatric	Impaired memory, paresthesia, mood impairment	Impaired cognitive function, delayed relaxation of tendon reflexes, depression,[a] dementia,[a] ataxia,[a] carpal tunnel syndrome and other nerve entrapment syndromes,[a] myxedema coma[a]
Gastrointestinal	Constipation	Reduced esophageal motility, nonalcoholic fatty liver disease,[a] ascites (very rare)
Endocrine	Infertility and subfertility, menstrual disturbance, galactorrhoea	Goiter, glucose metabolism dysregulation, infertility, sexual dysfunction, increased prolactin, pituitary hyperplasia[a]
Musculoskeletal	Muscle weakness, muscle cramps, arthralgia	Creatine phosphokinase elevation, Hoffman syndrome,[a] osteoporotic fracture[a] (most probably caused by overtreatment)
Hemostasis and hematological	Bleeding, fatigue	Mild anemia, acquired von Willebrand disease,[a] decreased protein C and S,[a] increased red cell distribution width,[a] increased mean platelet volume[a]
Skin and hair	Dry skin, hair loss	Coarse skin, loss of lateral eyebrows,[a] yellow palms of the hands,[a] alopecia areata
Electrolytes and kidney function	Deterioration of kidney function	Decreased estimated glomerular filtration rate, hyponatraemia[a]

[a] Uncommon presentation.
(From Chaker L, Bianco AC, Jonklaas J, et al. Hypothyroidism. *Lancet*. 2017;390:1550–1562.)

who were euthyroid, and poor memory was noted in 18% of those with hypothyroidism versus 16% of those who were euthyroid.[16] This has the dual consequences that individuals with these symptoms may be more likely to be suspected of having hypothyroidism, and that individuals with these symptoms may be diagnosed with hypothyroidism because they were screened, even if hypothyroidism was not the proximate cause of their symptoms. In addition to those symptoms mentioned earlier, other symptoms may include cold intolerance, hair loss, brittle hair and nails, muscle cramps, weakness, inability to concentrate, depression, and menometrorrhagia. In the same study as the one providing the percentages earlier, a change in symptoms in those with hypothyroidism compared with those who were euthyroid (such as being colder than the previous year or being more constipated than the previous year) had a higher likelihood ratio for hypothyroidism.[16] High likelihood ratios were evident for having a hoarser voice than the previous year (likelihood ratio 5.2; 95% confidence interval [CI]: 2.1–12.6) and finding math more difficult than the previous year (likelihood ratio 5.4, 95% CI: 2.2–13.1).

Interestingly, these types of symptoms are prevalent in those with Hashimoto hypothyroidism, even in the setting of euthyroidism. Furthermore, higher titers of thyroid peroxidase antibodies (TPO Abs) are associated with greater symptomatology.[17] For example, comparing euthyroid individuals with TPO Ab titers greater than or less than 121 IU/mL revealed statistically significant greater rates of chronic fatigue (66% vs. 49%), lack of concentration (32% vs. 19%), and nervousness (68% vs. 39%) in patients with higher titers.

Signs

Mild degrees of thyroid hormone deficiency may not result in obvious signs, except perhaps a firm goiter because of lymphocytic infiltration of the thyroid gland parenchyma. Over time, and with more decrement in thyroid hormone levels, cool and dry skin, coarse hair, loss of body hair, hoarse voice, coarse facial features, facial edema, generalized edema, bradycardia, and delayed relaxation phase of the deep tendon reflexes may be seen (Fig. 74.3). Extreme manifestations of these findings may be seen in myxedema coma.[18] Profound nail changes with horizontal ridges and marked hair loss may even occur with comparatively modest TSH elevations of 30.5 mIU/L and then be reversed with restoration of euthyroidism.[19] Manifestations of other autoimmune diseases such as vitiligo or hyperpigmentation may coexist with those of hypothyroidism.

KEY POINTS: Clinical Manifestations

- Signs and symptoms of hypothyroidism emanate from all the organ systems of the body.
- Symptoms of hypothyroidism overlap with symptoms of other conditions.
- Sign and symptoms of hypothyroidism extend across a wide spectrum from barely discernible to severe.

ETIOLOGY

The most common cause of hypothyroidism, in which the thyroid gland itself fails, is referred to as primary hypothyroidism. Primary hypothyroidism is generally considered "overt" when the TSH is elevated and the FT4 is low. Milder degrees of hypothyroidism, also known as SCH, are defined by an elevated TSH accompanied by a FT4 concentration that has not yet fallen below the normal range. Secondary or central hypothyroidism occurs when there is deficient production of TSH and is a much less common cause of hypothyroidism. Rarer causes of hypothyroidism also exist, such as TRH deficiency, thyroid dysgenesis, and "consumptive" hypothyroidism[15] (Table 74.2).

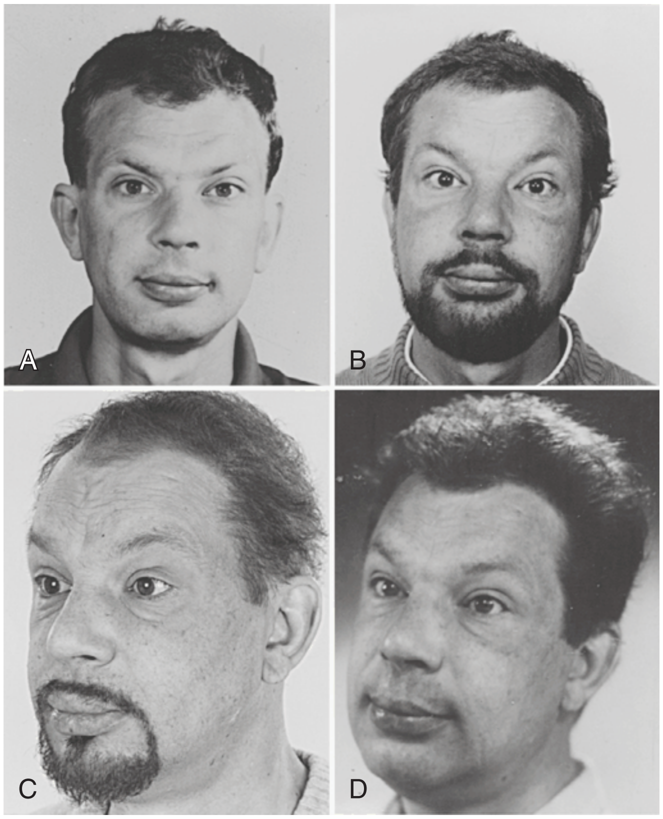

Fig. 74.3 Appearance of a 47-year-old man 12 years (A), 5 years (B), and 3 years (C) before hypothyroidism secondary to atrophic myxedema (D) was diagnosed. Note the typical myxedema face characterized by puffy, nonpitting swelling of the skin and coarse facial features.

Primary Hypothyroidism

Autoimmune Destruction. Among the causes of primary hypothyroidism, autoimmune (Hashimoto) thyroiditis is the most common cause in iodine-sufficient areas.[20] This is heralded by the presence of circulating TPO Abs, lymphocytic infiltration of the thyroid gland, and increased levels of TSH. Although the presence of TPO Abs is associated with an increased risk of progression to hypothyroidism, not all individuals with such positivity develop hypothyroidism. The pathology of Hashimoto thyroiditis involves infiltration of the interstitium around thyrocytes with lymphocytes, plasma cells, and macrophages.[20] The lymphocytes organize into lymphoid follicles, and lymphocytes that come into close contact with the thyrocytes are believed to mediate their destruction. There is also ongoing fibrosis, and the thyroid gland has a firm consistency upon palpation. Hashimoto thyroiditis can occur alone or in association with other autoimmune disorders, such as type 1 diabetes and pernicious anemia. Hashimoto thyroiditis is eight times more common in women than men, with a peak age of onset of 40 to 60 years. It occurs more frequently in White and Asian Americans than in Black Americans.

Drug-Induced. The list of medications that are associated with the development of hypothyroidism is ever-expanding. A partial list is included in Table 74.2.[15] Some of these drugs can also alter the requirement for thyroid hormone in individuals already receiving LT4 replacement therapy. Generally the effect is to cause an increased requirement. With respect to inducing the *de novo* development of hypothyroidism, several mechanisms may be responsible, such as altering thyroid hormone metabolism, altered thyroid-binding proteins, causing damage

TABLE 74.2 Causes of Hypothyroidism

Primary Hypothyroidism

- Chronic autoimmune thyroiditis (also known as Hashimoto thyroiditis)
- Iodine—severe iodine deficiency, mild and severe iodine excess
- Drugs—for example, amiodarone, lithium, tyrosine kinase inhibitors, interferon-α, thalidomide, monoclonal antibodies (e.g., ipilimumab and nivolumab), antiepileptic drugs (e.g., valproate), drugs for second-line treatment of multidrug-resistant tuberculosis
- Iatrogenic—radioiodine treatment (e.g., for Graves disease or toxic nodular disease), hemithyroidectomy, radiotherapy or surgery in the neck or head region
- Transient thyroiditis—viral (de Quervain syndrome), postpartum, silent thyroiditis, destructive thyroiditis
- Thyroid gland infiltration[a] —infectious (e.g., mycoplasma), malignant (e.g., thyroid malignancy, lymphoma, metastasis of malignancy elsewhere), autoimmune (e.g., sarcoidosis), inflammatory (e.g., Riedel thyroiditis)
- Genetic[a] —autoimmunity-related genes (e.g., *HLA* class 1 region, *PTPN22*, *SH2B3*, and *VAV3*), general and thyroid-specific genes (e.g., *F0XE1*, *ATXN2,* and *PDE86*)

Central Hypothyroidism

- Pituitary tumors (secreting or nonsecreting)
- Pituitary dysfunction (e.g., Sheehan syndrome)
- Hypothalamic dysfunction (e.g., posttraumatic)
- Resistance to thyroid-stimulating hormone (TSH) or thyrotropin-releasing hormone
- Drugs (e.g., dopamine, somatostatins, glucocorticosteroids, and retinoid X receptor-selective ligands)
- Increased TSH concentration because of leptin stimulation[b]

Peripheral (Extrathyroidal) Hypothyroidism

- Consumptive hypothyroidism
- Tissue-specific hypothyroidism owing to decreased sensitivity to thyroid hormone (e.g., mutations in *MCT8* [also known as *SLC16A2*], *SEQSBP2*, *TH RA*, *TH RB*)

[a] Rare cause of primary hypothyroidism.

[b] Evidence mainly from animal models.

(From Chaker L, Bianco AC, Jonklaas J, et al. Hypothyroidism. *Lancet*. 2017;390:1550–1562.)

to thyroid gland parenchyma or vasculature, decreasing TSH production, enhancing autoimmunity, or supplying iodine or agents with an iodine-like action. One class of drugs that is frequently associated with the development of hypothyroidism is anti-cancer drugs. Agents associated with the development of hypothyroidism include immune checkpoint inhibitors, tyrosine kinase inhibitors, interferon-α, and interleukin-2.[21]

Other Processes Resulting in Destruction of the Thyroid Gland. There are several iatrogenic means by which the thyroid gland can be destroyed. These include surgery, radioactive iodine given as treatment for hyperthyroidism or thyroid cancer, and radiotherapy for head and neck malignancies. In the case of a hemithyroidectomy, the relative risk of developing hypothyroidism is approximately 30%.[22] Infiltration of the thyroid gland associated with a spectrum of disease processes, such as sarcoidosis, hemochromatosis, hematologic malignancies, solid malignancies, and infectious agents can impair functioning to a sufficient degree to cause hypothyroidism.

Thyroiditis. Thyroiditis can be transient and cause temporary hypothyroidism, as the second phase of a three-phase process (hyperthyroidism, hypothyroidism, euthyroidism). Causes include granulomatous, postpartum, and silent thyroiditis. Alternatively, the thyroiditis can be more widespread and not associated with recovery, as may occur in silent thyroiditis in those who already have lymphocytic infiltration of their thyroid gland, and in Riedel thyroiditis.

Iodine Deficiency or Excess. The effect of iodine on thyroid function is complex. Not only is there a U-shaped curve, with insufficient iodine causing hypothyroidism and excessive iodine causing hyperthyroidism, but also introduction of iodine supplementation programs can enhance autoimmunity and change the pattern of thyroid diseases in a country.[23,24] Iodine deficiency is associated with elevation of serum TSH levels and development of diffuse and nodular goiter as the thyroid axis attempts to maintain adequate thyroid functioning by increasing iodine uptake, accompanied also by enhanced iodine recycling. As the degree of iodine deficiency worsens it can lead to hypothyroidism caused by failure of the compensation mechanisms leading to lack of the substrate needed for thyroid hormone synthesis. Addition of iodine to salt is an inexpensive and effective means of providing adequate dietary iodine. Because of iodine fortification programs, the areas of the world affected by iodine deficiency have decreased.

Exposure to iodine, in addition to reversing hypothyroidism as described earlier, can also induce hypothyroidism in those with predisposing risk factors such as prior episodes of thyroiditis or Hashimoto thyroiditis.[24,25] One way in which iodine exposure can occur is in the form of iodinated contrast media.[26] With the exposure to iodine, a normal thyroid gland will exhibit decreased thyroid hormone synthesis (Wolff–Chaikoff effect), followed by resumption of normal thyroid hormone synthesis (escape from the Wolff–Chaikoff effect). However, a gland affected by Hashimoto thyroiditis may not resume normal thyroid functioning (failure to escape from the Wolff–Chaikoff effect). In the former case of the normal gland, decreased sodium-iodine symporter expression, and possibly increased pendrin-mediated iodine efflux,[27] appear to relieve the gland of the inhibitory effects of the high intrathyroidal iodine concentration, whereas in the latter case of the gland affected by autoimmune thyroiditis, these counterregulatory mechanisms may not deploy.

Central Hypothyroidism

Secondary Hypothyroidism. Secondary hypothyroidism is characterized by insufficient TSH stimulation of a normal thyroid gland. This condition may be inherited because of several genetic defects, for which a number of candidates genes have been identified.[28] The acquired forms of secondary hypothyroidism include lesions in the sella turcica region (pituitary adenomas, craniopharyngioma, gliomas, etc.), pituitary damage owing to surgery or radiation, head injury, vascular accidents, drugs, and infiltrative processes (lymphocytic hypophysitis, sarcoidosis, hemochromatosis, infectious agents).[29]

Tertiary Hypothyroidism. In addition to pituitary dysfunction, hypothalamic dysfunction can also result in central hypothyroidism. Some of the candidate's genes associated with TSH deficiency may also be associated with TRH deficiency. Similar to the case with secondary hypothyroidism, tertiary hypothyroidism may be the consequence of hypothalamic lesions or hypothalamic injury because of surgery or radiation, head injury, vascular accidents, drugs, and infiltrative processes.[29]

Peripheral Causes of Hypothyroidism

Several rare conditions can be associated with impaired sensitivity to thyroid hormone. This was originally described as occurring with alterations in the *THRA* and *THRB* genes, but the discovery of genetic mutations and polymorphisms causing alterations in cell membrane transport (e.g., MCT8) and metabolism (e.g., selenocysteine insertion sequence–binding protein 2 and type 2 deiodinase) of thyroid hormone have led to a broader definition of impaired sensitivity to thyroid hormone that includes many defects that could interfere with the activity of thyroid hormone. Because of the different functions and tissue-specific expression of these genes, affected patients exhibit highly variable phenotypes. Some of them are characterized by a tissue hypothyroidism with well-recognizable alterations in the thyroid function tests, but others display a combination of hypothyroid and hyperthyroid manifestations.[30]

In addition to mutations causing tissue-specific hypothyroidism, an interesting and also rare cause of peripheral hypothyroidism is "consumptive hypothyroidism." This is a paraneoplastic syndrome in which a tumor produces excessive levels of the type 3 deiodinase, leading to markedly increased degradation of T4 and resultant low T3 levels, high reverse T3 levels, and elevated TSH. Large doses of LT4 are generally required until the tumor can be resected. Although originally described in tumors of vascular origin (hepatic hemangiomatosis) in infants, cases have now been described in adults because of both vascular and nonvascular tumors.[31]

KEY POINTS: Etiology

- The commonest cause of hypothyroidism is autoimmune destruction of the thyroid gland.
- Processes interfering with hypothalamic or pituitary function are less common causes of hypothyroidism.

DIAGNOSIS

Diagnosis of thyroid "disease" is based on a thyroid parameter (TSH, FT4, T3, etc.) confirmed as being outside its reference interval, combined with the signs and symptoms that would be anticipated for these "out of range" values.

Reference Intervals

As for any other analyte, the reference interval for a thyroid analyte is derived from the 95% confidence intervals for that particular analyte established in at least 120 normal volunteers.[32] These reference intervals, or decision limits, are provided to try to aid in interpretation of test results. Laboratories typically generate their own reference interval based on their local population. Theoretically, this should be a healthy population, and a minimum of 120 individuals should contribute to the database. Ensuring a healthy population without thyroid disease would involve, for example, excluding individuals with TPO Abs, those taking interfering medications, and those with goiters. If a different reference interval were deemed appropriate for a particular subpopulation, for example men versus women, this would require 120 individuals for each sex.

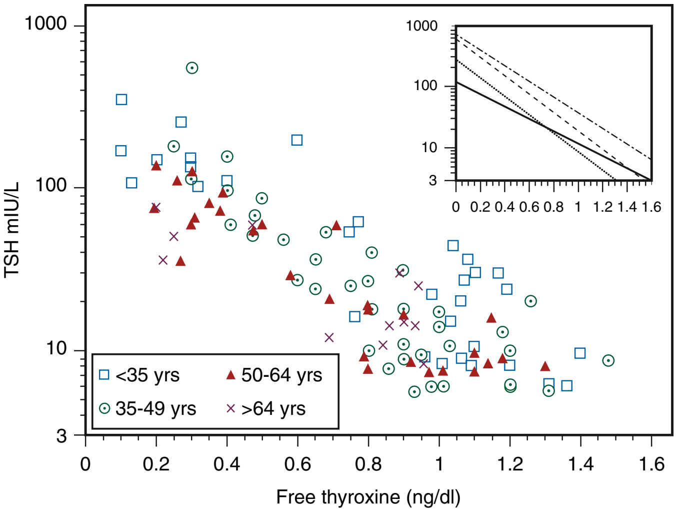

Fig. 74.4 Relationship between free thyroxine and thyroid-stimulating hormone (*TSH*) in a group of patients with hypothyroidism according to age. For all patients together the Spearman correlation coefficient = –0.795, $P < .0001$. The insert shows the slopes within the four age groups: dots and dashes <35 years, dashes 35–49 years, dots 50–64 years, solid line >64 years. *FT4*, Free thyroxine. (From Over R, Mannan S, Nsouli-Maktabi H, et al. Age and the thyrotropin response to hypothyroxinemia. *J Clin Endocrinol Metab.* 2010;95:3675–3683.)

These reference intervals are then used by various agencies to make recommendations about categorization or decisions based on the reference intervals. Given the consequences that may occur depending on the exact limits of these reference intervals, it is critical for clinicians to appreciate the factors that can influence these reference intervals. The bounds of a reference interval can, for example, result in making diagnoses that have minimal consequences or missing diagnoses in which intervention would be of benefit.[33] Natural variations in thyroid parameters such as circadian rhythms, body mass index or weight, season, and climate can potentially affect reference intervals. In addition, age, sex, thyroid hormone assays, race and ethnicity, and iodine status can also affect reference intervals.

Serum Thyroid-Stimulating Hormone

The most commonly measured thyroid analyte is the serum TSH concentration. Hypothyroidism and hyperthyroidism are diagnosed when the TSH is confirmed to be above and below the limits of the reference interval, respectively. The effect of age on the reference interval is a particularly important issue for TSH. Serum TSH concentrations tend to rise with age, such that the upper limit of the reference interval is higher in older individuals. This is a very important consideration, as the benefits of thyroid hormone treatment for mild TSH elevations are not well established in older age groups. TSH assays, however, may detect abnormal TSH isoforms with different amounts of glycosylation, such as those that may be associated with TSH-secreting pituitary tumors or normal aging.[34] Altered glycosylation can cause a mismatch between TSH concentrations and TSH bioactivity. Several factors can interfere with measurement of TSH. For example, consumption of biotin can cause TSH values to be falsely measured as low, whereas heterophilic antibodies can cause TSH values to be falsely measured as high.[35]

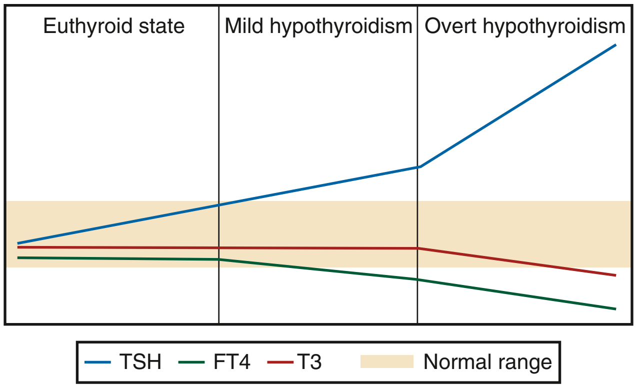

Fig. 74.5 The progression of hypothyroidism. *TSH,* Thyroid-stimulating hormone; *FT4*, free thyroxine; T3, triiodothyronine.

Log-Linear Relationship

Measurement of serum TSH is considered an ideal screening test for thyroid dysfunction, as there is an inverse log/linear relationship between TSH and FT4. This means that a small alteration in FT4 will produce a far larger change in serum TSH, thereby signaling even mild perturbations in FT4. Thus, even though TSH measurement is an indirect assessment of FT4, it is generally more sensitive for assessing thyroid dysfunction than is measuring FT4. Reliance on TSH as an indicator of thyroid status assumes that the pituitary is functional, that the individual is not suffering from a nonthyroidal illness, and that thyroid status is stable. When thyroid status is unstable, the serum TSH concentrations may lag behind the clinical picture. As previously mentioned, the TSH–FT4 relationship may be more complex than a simple linear one, with the slope being affected by sex, age, genetics, and use of LT4. For example, younger individuals may mount a more vigorous TSH response to low FT4 values than older individuals[36] (Fig. 74.4).

Free Thyroxine Levels

FT4 measurements by immunoassay are affected by protein binding and may be less accurate at extremes of binding protein concentrations, such as may occur during pregnancy. Results of FT4 measurement may be anomalous in the presence of albumin variants (e.g., familial dysalbuminemic hyperthyroxinemia), in the presence of medications that displace thyroid hormone from thyroxine-binding globulin (e.g., phenytoin or carbamazepine), or in the context of critical illness. FT4 may also be measured after free hormone has been separated from bound hormone using equilibrium dialysis or ultrafiltration. Such methods are more time-consuming and generally are less readily available. Other forms of interference include interfering antibodies, a problem that can be bypassed by using tandem mass spectrometry–based assays rather than immunoassays.[37] *In vitro* drug interference can also occur, such as the in the case of heparin causing *in vitro* generation of free fatty acids, displacement of thyroid hormone from binding proteins, and false elevation of FT4 values.[35]

FT4 levels below and above the limits of the reference limit are consistent with hypothyroidism and hyperthyroidism, respectively. Although the gold standard for assessing thyroid status has been considered to be serum TSH, some studies suggest that thyroid hormone levels may be important too. A recent systematic review found that clinical parameters representing the cardiac, bone, and metabolism systems were more associated with FT4 levels than TSH levels, suggesting that further research is needed to understand the importance of thyroid hormone levels as an indicator of thyroid status.[38]

Triiodothyronine Levels

If measuring T3, it is generally better to measure total T3 rather than free T3 because of the low concentrations of free hormone present and the lesser performance of immunoassays at these lower concentrations. Concentrations of total T3 are affected by binding protein abnormalities, as might occur with estrogen therapy and during pregnancy, and can also be affected by autoantibodies to thyroid hormone. An accurately measured elevated total T3 that is above the upper limit of the reference interval is consistent with hyperthyroidism. A total T3 that is below the lower limit of the reference interval is not necessarily sensitive or specific for hypothyroidism (Fig. 74.5). This is because total T3 levels fall later than FT4 levels in the course of development of hypothyroidism because of enhanced T4 to T3 conversion, and also because T3 levels are lowered by illness, poor nutrition, and several drugs such as beta-blockers and glucocorticoids.

Thyroid Antibody Testing

With the previously described Hashimoto disease, TPO Abs and thyroglobulin antibodies are generally present in the serum, precede the development of thyroid dysfunction, and signal the ongoing cellular damage to the thyroid gland that is occurring as hypothyroidism develops. Occasionally patients may have autoimmune thyroid disease with negative antibody results. TPO Abs are a risk factor for progression into hypothyroidism over time, and also for developing hypothyroidism after treatment with agents such as amiodarone, lithium, and interferon-α. Although changes in TPO Ab titers may reflect a change in disease activity, they are not useful for monitoring treatment for hypothyroidism. The presence of TPO Abs, however, is helpful for predicting the development of hypothyroidism during pregnancy, as well as the risk of miscarriage and the failure of *in vitro* fertilization. The presence of TSH receptor antibodies is useful for the evaluation of patients with hyperthyroidism.

Detection of Central Hypothyroidism

If central hypothyroidism caused by pituitary or hypothalamic dysfunction is suspected, reliance on the serum TSH values for diagnostic purposes is no longer indicated. A low or low normal TSH in the setting of a low FT4 should raise the possibility of central hypothyroidism. Further evaluation should include a careful patient history, the assessment of other pituitary axes, and imaging of the pituitary and sella area.[39]

Subclinical Versus Overt Hypothyroidism

SCH has generally been defined as an elevation in the serum TSH level above the upper limit of the reference interval, with a FT4 concentration that remains in the normal range. When making a determination of whether SCH is present, the reference interval being used clearly impacts the diagnosis. In the literature, upper limits of normal that have been used include TSH values of 3, 4, 5, and 6 mIU/L. Clearly, these chosen cutoffs are based on the reference interval for the particular TSH assay used, which is in turn defined by the laboratory that is providing the assay. The reference population employed by the laboratory may not be fully described, and standardized collection procedures are often not used.[40] The statistical methods used also affect the results.[41] The particular cutoff value for a normal TSH used in any one study will determine the prevalence of SCH that is identified. This choice has consequences in terms of both detection and classification of thyroid disease. Lower TSH cutoffs will have the downstream effect of identifying a greater number of individuals with SCH in whom potential treatment may be considered. An additional very important consideration before diagnosing SCH is confirming the TSH elevation.

Many above-range TSH values revert to normal upon follow-up, with the rate of normalization being inversely proportional to the degree of the TSH elevation above normal.[33]

Screening

The US Preventive Services Task Force does not recommend routine screening of adults for thyroid disease.[42] Other organizations differ as to whether they recommend routine screening or case-finding in older, asymptomatic individuals. However, with respect to criteria for population screening, hypothyroidism is prevalent and an important health problem. Moreover, diagnosis is simple and accurate, and treatment is efficacious, cost-effective, and safe. Confounding the issue are the possibilities that screening and early diagnosis may either only detect degrees of hypothyroidism that are mild and for which the benefits of treatment are less well documented or may detect disease for which treatment results in significant benefit. Although routine screening for thyroid dysfunction has not been shown to be of benefit for asymptomatic nonpregnant adults, mounting evidence suggests metabolic, cardiovascular, and skeletal risks in populations with TSH values above the normal range.[43,44] Although the benefits of treatment of overt hypothyroidism are undisputed, positive results from randomized controlled trials of treating SCH would bolster the case for screening.[45]

Normal Thyroid-Stimulating Hormone With Symptoms Overlapping With Hypothyroidism

Because symptoms of hypothyroidism are nonspecific and overlap with symptoms of other conditions, even if an individual is found to have hypothyroidism following screening based on symptoms, the symptoms may or may not resolve with initiation of LT4. Thus, the symptoms may have led to the diagnosis of hypothyroidism, despite the fact that hypothyroidism was not the cause. Individuals with a normal serum TSH who have symptoms overlapping with symptoms of hypothyroidism do not have resolution of these symptoms with LT4 therapy.[46]

KEY POINTS: Diagnosis

- Primary hypothyroidism is diagnosed based on the exponential rise in thyroid stimulating hormone that signals declining thyroid hormone levels.
- Accurate measurement of thyroid analytes is essential for correct diagnosis of hypothyroidism.
- Mild disease may apparently have relatively few consequences if undiagnosed.
- If overt hypothyroidism remains undiagnosed, significant adverse health consequence can ensue.

TREATMENT

Although there are some causes of hypothyroidism that are associated with recovery from the hypothyroid condition (thyroiditis, drug-induced hypothyroidism, iodine deficiency), most cases of hypothyroidism are associated with a lifelong need for thyroid hormone. Moreover, despite the interest in alternative therapies such as diets and nutritional supplements, the only known treatment for hypothyroidism is provision of thyroid hormone.

Levothyroxine Therapy

Use of LT4 is, in many respects, an ideal form of drug therapy. LT4 is inexpensive, chemically similar to endogenous T4 and absorbed well when administered orally and has a long enough duration of action to permit once-daily administration. With very rare exceptions, side effects seem to be related to use of inadequate or excessive doses of LT4.

Initiation of Therapy. At the time of their diagnosis with hypothyroidism, individuals may have varying degrees of residual thyroid function. Based on the relationship between declining thyroid hormone levels and stimulation of TSH production, those with SCH would still have substantial endogenous thyroid reserve, whereas those with overt hypothyroidism would have remaining endogenous thyroid function ranging from a complete absence to modest amounts. With respect to initiation of LT4 therapy, this can generally be started at a full replacement dose, so that biochemical derangements are more quickly reversed. This method does not appear to be associated with adverse cardiac consequences in those without underlying cardiac disease.[47] Recommended exceptions to immediate full replacement are noted later under “Specific Situations.”

At least two general approaches can be taken to starting doses of LT4 for replacement, both generally leading to similar estimates. One approach is to select the starting dose based on the degree of TSH elevation. Several formulae are available for guidance, should that approach be taken.[48,49] The more common approach, however, is to calculate the starting dose using a weight-based formula. Assuming little or no residual thyroid function, weight-based replacement doses are on the order of 1.6 to 1.8 mcg/kg.[7] The purest example of this would be a patient who is athyreotic as the result of a thyroidectomy.[50] More accurate estimates may be obtained if ideal body weight or lean body mass are used, rather than actual body weight.[7,51] The consequence of this may be that, if actual body weight is used in an overweight or obese individual, then the dose selected may be too high. The required dose may also be affected by the TSH goal of the treatment, with higher doses needed to achieve TSH values in the lower half of the normal range.[7] The effect of age is generally to decrease a patient’s anticipated requirement, and this phenomenon may be mediated through body weight.[52] Pregnancy will also lead to an increased requirement for LT4, such that dosage increases are needed to maintain a normal serum TSH.

Adjustment of Therapy. LT4 has a half-life of approximately 1 week, such that a new steady state with respect to thyroid parameters (TSH, FT4, T3) is generally achieved by 6 weeks after a dosage initiation or a dosage change. Based on this reassessment of thyroid status, the LT4 can be adjusted up or down and thyroid parameters rechecked in a further 6 weeks. If the TSH is outside of the desired range by a modest amount, an adjustment by one dosage increment (e.g., from 100 mcg to 112 mcg) may be sufficient. For larger deviations from the desired range, an increase of several increments may be needed. Although simple dosage regimens are preferable to facilitate adherence, some patients may require alternating doses (such as 137 mcg alternating with 150 mcg) or may need small adjustments that can be achieved by taking a half tablet or one-and-a-half tablets on one day of the week, while taking the usual one tablet on the other days of the week. Once a patient has achieved the desired serum TSH level, a confirmation that the TSH remains normal at 3 or 6 months may be indicated. However, once a correct dose has been confirmed, usually monitoring of serum TSH and FT4 on an annual basis is sufficient. Additional or earlier laboratory testing to confirm the euthyroid state may be needed if a patient has gained or lost a significant amount of body weight, or if the patient has new medical conditions or new medications that might affect their requirement for LT4.

Although the gold standard for assessing thyroid status has been considered to be the serum TSH, some studies suggest that thyroid hormone levels may be important too. As previously mentioned, a recent systematic review found that clinical parameters representing the cardiac, bone, and metabolism systems were more associated with FT4 levels than TSH levels, suggesting that further research is needed to understand the importance of monitoring and potentially adjusting therapy based on thyroid hormone levels as well as TSH levels.

Goals of Therapy

Standard-of-Care Goals. The goals of treating hypothyroidism are to restore the patient to a euthyroid status by reversing the signs and symptoms of hypothyroidism and restoring the patient's TSH and thyroid hormone levels to normal. The biochemical goals are readily achieved, although T3 levels, if assessed, may be in the lower part of the normal range, particularly in athyreotic patients.[53] With respect to signs of hypothyroidism, although weight gain is associated with the hypothyroid state, reversal of hypothyroidism, although achieving a median TSH that was decreased from 18.3 mIU/L to 2.3 mIU/L, was not associated with any weight loss.[54] Even treatment of more severe hypothyroidism, despite lowering the TSH from 102 mIU/L to 2.2 mIU/L, was associated only with a weight loss of 4.3 kg. This was not caused by a decrease in fat mass, but a decrease in the mass of the lean body compartment only.[55] Although symptoms may improve following LT4 therapy, they may not reach the level of improvement anticipated if the control population is used as the comparison. For example, in a study in which quality of life was assessed using a thyroid specific instrument (ThyPRO), after 6 months of therapy, during which the median TSH was decreased from 8.1 mIU/L to 2.6 mIU/L, improvement was noted in 11 out of 13 subscales compared with baseline, but was only improved compared with the general population in seven out of 13 subscales.[56] Additional goals are to avoid iatrogenic hypothyroidism or iatrogenic hyperthyroidism, which unfortunately occurs in up to 40% of patients being treated for hypothyroidism.[57,58]

Avoidance of long-term iatrogenic hypothyroidism or hyperthyroidism is desirable in all patients treated for hypothyroidism. However, this is particularly important in vulnerable populations such as patients who are pregnant, elderly, or have cardiac disease and other medical conditions. Thus, the ideal TSH value for a particular patient may depend on the patient's age, coexisting medical conditions, and any benefits that may be associated with specific TSH values. A particular TSH target can be achieved by serial adjustment of a patient's LT4 dose. Maintenance of that TSH should then be possible with continuation of that same dose if no other influences act to perturb the equilibrium. Despite such ease of adjustment, many patients with hypothyroidism have out-of-range TSH values. Of a population attending a health fair, 18% were receiving inadequate LT4 therapy, and 22% were receiving excessive LT4 therapy.[58] Other studies show similar percentages of patients with abnormal TSH values.[7] This is particularly a problem in those over 65 years of age, where iatrogenic thyrotoxicosis is especially common.[57] This is of particular concern in patients with comorbidities, which primarily affect elderly patients. One risk of overtreatment with LT4 is adverse effects on the heart, which manifest as decreased cardiac reserve and impaired exercise capacity, and, based on data from populations with both exogenous and endogenous hyperthyroidism, an increased risk of atrial fibrillation. The other major adverse consequence is accelerated bone loss, which may be compounded by hypogonadism in the elderly. Undertreatment with LT4 is also associated with adverse outcomes. Whenever possible, therapy should be adjusted to avoidance iatrogenic hypothyroidism or hyperthyroidism. Serum TSH should be checked annually, and perhaps more frequently in those who have a history of dose instability. Alterations in weight, as well as new medical comorbidities, medications, or symptoms should also trigger consideration of whether repeat laboratory assessment is indicated.

Additional Goals. Other goals of therapy should also be considered. In two studies funded by a pharmaceutical company, frequent LT4 dosage changes were associated with lost time and wages for patients, with reduced patient satisfaction. Based on these studies, it would seem to be important to ensure stability of treatment by minimizing influences that may lead to changing dose requirements.[59,60]

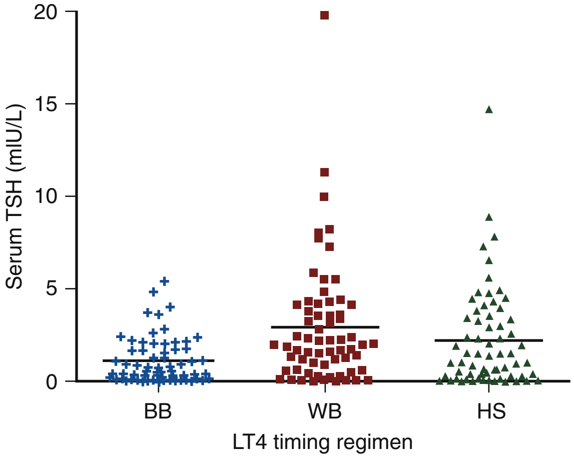

Fig. 74.6 **The effect of the timing of levothyroxine (LT4) administration on serum thyroid-stimulating hormone (*TSH*).** (From Bach-Huynh T, Nayak B, Loh J, et al. Timing of levothyroxine administration affects serum thyrotropin concentration. *J Clin Endocrinol Metabol.* 2009;94:3905–3912.)

Optimization of Therapy. A consistent schedule for daily administration of LT4 seems desirable to facilitate adherence.

Scheduling of Levothyroxine. More important than the particular time that is identified for taking LT4 is maintaining a regular schedule so that absorption varies as little as possible and so that doses are not omitted.[7] Potential times for LT4 administration are 60 or 30 minutes before breakfast, with breakfast, and at bedtime. A wealth of studies have compared these regimens, and in general the schedules that are most associated with maintaining a TSH that is consistently within the normal range are 60 minutes before breakfast and at bedtime[61] (Fig. 74.6). Taking LT4 with breakfast results in the most variation in serum TSH. A consistent schedule should be adopted that is convenient to the patient and the least disruptive to their daily routine. Regimens that involve the patient awakening early from sleep do not seem optimum. The use of a prefilled tablet container is encouraged, particularly for those individuals who are taking multiple medications. If an LT4 dose is omitted, the options include taking the dose are soon as the omission is noted or taking two doses the following day.

Absorption of Levothyroxine. LT4 absorption occurs mostly in the jejunum and ileum. The maximum absorption of LT4 is approximately 75% to 80%, and this occurs when the patient consumes LT4 in a fasting state. The presence of an acidic environment in the stomach also seems to promote absorption.[7] Any food that is coadministered with LT4 can potentially reduce its absorption. Soy products, fiber, and milk, for example, can reduce absorption. Beverages such as Italian espresso can also impair absorption. The manifestation of impaired absorption is an elevated TSH. Medications and supplements are also known to reduce absorption, with common culprits being calcium carbonate, iron, multivitamins, and proton pump inhibitors[62-64] (Table 74.3). Calcium carbonate and iron seem to impair LT4 absorption by adsorbing to LT4 in the stomach. Proton pump inhibitors may exert their effects by reducing stomach acidity. Vitamin C stands alone as the one product that increases LT4 absorption and may have this effect by virtue of increasing stomach acidity. A particular example where the reduced LT4 absorption could have adverse effects for the patient is that seen when LT4 is given concurrently with enteral tube feeds in a hospitalized patient.[65] The impaired absorption associated with foods, beverages, and medications may be overcome by changing the time of the LT4 administration, or a higher dose of LT4 may be administered to compensate for the effect of the decreased absorption.

TABLE 74.3 Medical Conditions, Foods, and Drugs Affecting Levothyroxine (LT4) Absorption

Factor	Strength of Evidence	Result of Interaction (Clinical Significance)	Recommendation
Disorder			
Celiac disease	Very good	↑↑ need for LT4 (clinically significant)	Caution during treatment because of iatrogenic hyperthyroidism
Lactose intolerance	Very good	↑↑ need for LT4 (clinically significant)	Caution during treatment because of iatrogenic hyperthyroidism
Atrophic gastritis and *Helicobacter pylori*	Very good	↑↑ need for LT4 (clinically significant)	Caution during treatment because of iatrogenic hyperthyroidism
Giardiasis	Poor	↑↑ need for LT4 (clinically significant)	Caution during treatment because of iatrogenic hyperthyroidism
Bariatric surgery*	Controversial	↑/↓ need for LT4 (clinically significant)	Monitor thyroid hormones after surgery
Food			
Fiber	Controversial	↑ need for LT4 (clinically significant)	Avoid concomitant use
Soybeans	Very good	↑↑ need for LT4 (clinically significant)	Avoid concomitant use
Coffee*	Very good	↑↑ need for LT4 (clinically significant)	Avoid concomitant use
Grapefruit	Good	↑ need for LT4 (clinically significant)	Avoid concomitant use
Vitamin C[†]	Very good	↓↓↓ need for LT4 (clinically significant)	Can improve absorption
Drug			
Aluminum hydroxide	Very good	↑↑ need for LT4 (D)	Avoid concomitant use for >2 h
Calcium salts	Very good	↑↑ need for LT4 (D)	Avoid concomitant use for at least 2 h
Iron preparations	Very good	↑↑ need for LT4 (D)	Avoid concomitant use as much as possible
Lanthanum	Very good	↑↑ need for LT4 (D)	Avoid concomitant use
Orlistat	Controversial	↑↑↑ need for LT4 (D)	Avoid concomitant use for at least 2 h
Polystyrene sulfonate	Poor	↑↑↑ need for LT4 (D; moderate)	Avoid concomitant use
Raloxifene	Good	↑↑ need for LT4 (D; minor)	Avoid concomitant use as much as possible
Bile acid sequestrants	Very good	↑↑↑ need for LT4 (D; moderate)	Avoid concomitant use as much as possible
Sevelamer	Very good	↑↑↑ need for LT4 (D; moderate)	Avoid concomitant use
Simethicone	Poor	↑↑ need for LT4 (D; moderate)	Avoid concomitant use
Ciprofloxacin	Very good	↑↑↑ need for LT4 (C; moderate)	Avoid concomitant use
Rifampicin	Very good	↑/↓ need for LT4 (C; moderate)	Monitor thyroid hormones
Sucralfate	Controversial	↑↑↑ need for LT4 (C; moderate)	Avoid concomitant use
Chromium	Very good	↑ need for LT4 (B; moderate)	Monitor thyroid hormones
H_2-receptor antagonists	Controversial	↑ need for LT4 (B)	Monitor thyroid hormones
Proton pump inhibitors[a]	Good	↑↑ need for LT4 (B; moderate)	Monitor thyroid hormones

↑ = increase; ↓ = decrease.

Interaction was refuted for soft gel capsules and liquid form of LT4.

[a] Patients with impaired absorption.

(From Skelin M, Lucijanić T, Amidžić Klarić D, et al. Factors affecting gastrointestinal absorption of levothyroxine: a review. *Clin Ther.* 2017;39:378–403.)

In addition to decreased LT4 absorption being associated with the food and medications listed earlier, several gastrointestinal conditions may also be associated with a decrement in LT4 absorption. These include celiac disease, lactose intolerance, ulcerative colitis, and atrophic gastritis associated with *Helicobacter pylori* infection.[62,66] Patients with these conditions may require greater than the predicted weight-based LT4 dose before their treatment, but with resolution of the higher requirement if the condition is successfully treated. The balance of the competing effects of weight loss and malabsorption after bariatric surgery most commonly seems to result in patients requiring a reduced LT4 dose after surgery.[67]

Drugs Affecting Levothyroxine Dose. In addition to the drugs and conditions mentioned earlier that alter LT4 dose requirement by affecting, and usually reducing, absorption, a number of drugs may also alter LT4 dose requirement through their effects on LT4 transport and metabolism (Table 74.4). The classic examples of drugs affecting LT4 transport that increase and reduce the requirement for LT4, respectively, are estrogen and testosterone.[7,63] These influences occur because of the effects of these sex steroids to increase (estrogen) and decrease (testosterone) the concentration of thyroxine-binding globulin. LT4 is metabolized by deiodination, glucuronidation, and sulfation, and many drugs act to increase its metabolism. The conjugation with glucuronates and sulfates occurs in the liver, and several drugs act as hepatic enzyme inducers and enhance LT4 metabolism. Examples of such drugs are phenobarbital, phenytoin, carbamazepine, rifampin, and nicardipine.[7,68] Other drugs such as tyrosine kinase inhibitors may act by altering deiodinase activity. The increased TSH that occurs in previously euthyroid patients taking LT4 when drugs such as sunitinib and sorafenib are initiated appears to be caused by increased activity of

TABLE 74.4 Examples of Medications Causing Altered Transport or Metabolism of Levothyroxine (LT4)

Alteration in LT4 transport	Medication	Effect
Increased TBG	Estrogen	Increased LT4 requirement
	Capecitabine	Increased LT4 requirement
Decreased TBG	Androgens	Decreased LT4 requirement
Increased TBG or increased transport	Estrogen, raloxifene, tamoxifen, heroin, methadone, 5-fluorouracil, mitotane, clofibrate	May not cause thyroid dysfunction
Decreased TBG or decreased transport	Androgens, anabolic steroids, glucocorticoids, nicotinic acid, salicylates, furosemide, heparin, NSAIDs, phenytoin, carbamezepine	May not cause thyroid dysfunction
Alteration in LT4 Metabolism	**Medication**	**Effect**
Increased hepatic metabolism via induction of P450	Phenobarbital, rifampin, phenytoin, sertraline, carbamazepine	Can increase LT4 requirement or may not cause thyroid dysfunction
Decreased activation of T4 to T3 via inhibition of type 2 deiodinase	Beta-blockers, steroids, PTU, radiographic contrast agents, amiodarone	Can increase LT4 requirement or may not cause thyroid dysfunction
Increased deactivation of T4 and T3 via acceleration of type 3 deiodinase	Tyrosine kinase inhibitors (imatinib, sorafenib, motesanib, sunitinib)	Can increase LT4 requirement

TBG, thyroxine-binding globulin; *NSAID,* nonsteroidal antiinflammatory drugs; *PTU,* propylthiouracil.

the type 3 deiodinase, as evidenced by decreased T4 and T3 levels and increased reverse T3 levels.[69]

Levothyroxine Preparations. LT4 is available as tablet preparations and also as a liquid preparation, or as a liquid contained within a gel capsule. The various LT4 tablets include brand-name and generic preparations. The tablet preparations are all similar in the content of their active ingredient (LT4 itself) but differ with respect to their inert ingredients in the form of excipients (mixers, fillers, and colorants). The product that is most affordable to a patient may vary according to the patient's insurance company and pharmacy, and also may not stay constant over time. There are reports of significant changes in serum TSH when a patient's LT4 is changed either from one brand name to another, or from a brand name to generic product, or from one generic to another.[7] The altered TSH is thought to occur because the various products may have different absorption because of the different excipients. Because of their different absorption, each of these products has slightly different bioequivalence.

Bioequivalence is a measure of absorption or bioavailability that the US Food and Drug Administration (FDA) uses to predict therapeutic efficacy. Bioavailability is determined by studying the pharmacokinetics of large oral doses of LT4 in volunteers who have normal endogenous thyroid function.[7] Pharmacokinetic parameters including the maximum serum concentration (Cmax), time to Cmax, and area under the concentration-time curve (AUC) are used to compare different products. If the two 90% confidence intervals from the natural logarithms of the AUC at 48 hours and the Cmax are both within the 80% to 125% range, the products are deemed bioequivalent by the FDA and can be substituted for each other. Measures of systemic exposure (AUC, Cmax) are used in this testing, rather than clinically relevant or biochemical endpoints such as serum TSH levels. As such bioequivalence methodology does not detect LT4 doses with approximately 12.5% difference from each other (e.g., 100-mcg and 112-mcg tablets), it is always advisable to recheck serum TSH in individuals who have been switched from one preparation to another to be sure that iatrogenic hyperthyroidism or hypothyroidism has not developed and that the serum TSH is still in the target range.[7] Furthermore, where possible it is best to maintain a patient on the same "identifiable" product. The name of the manufacturer is on the label of the bottle, so patients can request LT4 made by the same manufacturer when obtaining refills.

Liquid LT4 preparations are available in the United States in which the LT4 is dissolved in glycerol and contained either within a gelatin capsule or in a solution. Liquid preparations are reported by the manufacturer to have 100% absorption from the gastrointestinal tract, compared with approximately 75% absorption in the fasting state for other LT4 preparations. The dissolution of the gelatin capsule preparation appears to be relatively unaffected by pH. Therefore, its absorption, in theory, might be less affected by the altered pH of the gastric environment associated with food consumption, atrophic gastritis, and use of proton pump inhibitors than other LT4 products. There is, in fact, a growing body of evidence that liquid preparations may have better absorption in situations where patients are receiving proton pump inhibitors[70] or tube feeds[71] or have other causes of malabsorption.[72] It is also plausible that gelatin capsules may be better tolerated than tablets in individuals with allergies to the excipients contained within tablet preparations.

Levothyroxine Therapy in Specific Situations

Pregnant Patients. During pregnancy it is recommended that patients being treated for hypothyroidism be frequently monitored so that their TSH values can be maintained in the lower half of the trimester-specific reference range. When such reference ranges are not available, a TSH below 2.5 mIU/L is a reasonable goal.[73] Women being treated for hypothyroidism typically require a 20% to 30% increase in their LT4 dose early in the first trimester of pregnancy. The magnitude of the increase is greater in thyroidectomized patients than in those with some residual thyroid function.

Pediatric Population. Treatment of hypothyroidism in the pediatric population is discussed elsewhere. The management of hypothyroidism in children is similar to its management in adults. However, there are special considerations based on the requirement of normal thyroid function for neurocognitive development as well as growth and development. As a reflection of their unique physiology, newborns, children, and adolescents typically require higher LT4 doses than adults. As an individual advances from childhood into adulthood, LT4 replacement doses decrease, with newborns typically requiring 10 mcg/kg/day, 1-year-old children 4 to 6 mcg/kg/day, and adolescents 2 to 4 mcg/kg/day, with transition to the average adult dose of 1.6 mcg/kg/day once endocrine maturation is complete.

Nonadherent Patients. If patients take a consistent dose of LT4, their serum TSH levels should remain within a fairly narrow range. If patients experience unexpected fluctuations in their serum TSH, or persistently elevated TSH concentrations despite the administration of large doses of LT4, factors affecting LT4 formulation, absorption, and metabolism should be investigated as potential causes. If, however, such factors do not appear to be responsible, variable adherence or nonadherence to LT4 therapy should be considered. Although one survey of patients prescribed LT4 found a self-reported nonadherence rate of 22%, a study of a large insurance claims database indicated nonadherence rates of 40% to 52%. Using another database, adherent patients had lower overall healthcare costs and less diagnosis of other diseases than nonadherent patients. However, it should be noted that the latter two studies were funded by a pharmaceutical company. Because LT4 is generally a lifelong medication, it is important for patients to identify a medication schedule that facilitates adherence. Patients may be taking multiple other medications, including those that require specific administration conditions (e.g., bisphosphonates) or those that impair absorption. It may be necessary to choose a schedule of medication administration that is practical, even if absorption is affected, if this ensures that doses are not omitted.

If a combination of a high TSH and a high-normal or high T4 concentration is documented by laboratory testing, this pattern could be consistent with the syndrome of thyroid hormone resistance, a TSH-secreting pituitary adenoma, or recent resumption of LT4 intake before a scheduled blood test. Intuitively, patient education regarding the benefits of euthyroidism and the risks of iatrogenic thyroid disease would seem to a logical approach to reducing nonadherence. However, a study providing education in the form of booklets mailed to patients' homes did not affect serum TSH, which was used as a surrogate marker of adherence. If efforts to encourage regular daily consumption of LT4 are unsuccessful, options include observed therapy, including twice weekly or weekly therapy. Weekly therapy is associated with supratherapeutic concentrations of FT4 for about 24 hours and elevated TSH levels prior to the administration of the weekly dose, although FT3 levels remain within the normal range, and patients appear not to report side effects. Parenteral administration of LT4 is also possible.

Central Hypothyroidism. When treating patients with hypothyroidism because of TSH deficiency, a parameter other than serum TSH is needed to guide LT4 replacement therapy. Based on a randomized trial comparing two doses of LT4, it has been recommended that FT4 levels be kept in the upper half of the normal range.[7] Slightly lower FT4 levels, perhaps in the mid-normal range, have been suggested for frail or older individuals.

Patients with Thyroid Cancer. A subgroup of patients who are intentionally kept with TSH values below the normal range are those with intermediate or high-risk differentiated thyroid cancer. Studies show either increased survival or increased relapse-free survival in these risk categories with TSH suppression, but not in patients with low-risk thyroid cancer, who can be maintained with a serum TSH in the lower half of the normal range. In higher-risk patients, the benefits of TSH suppression and the risks, such as potential bone loss and adverse cardiac effects, have to be balanced against potential benefits.

Older Patients and Patients With Medical Conditions. Patients older than 60 to 65 years of age, patients who have severe, longstanding hypothyroidism, or those with coronary artery disease need a gradual approach to LT4 replacement. In patients known to have ischemic heart disease, treatment should be initiated with lower doses of LT4 such as 25 mcg daily. In other patients at risk for coronary artery disease, but without documentation of such disease, a conservative starting dose of approximately 50 mcg per day may be advisable. This caution would apply to patients who are in older age groups or who have had longstanding severe hypothyroidism. Older individuals may have other chronic medical conditions that may require altered doses of LT4 to maintain a normal TSH. In addition, euthyroidism should be carefully maintained to avoid iatrogenic thyroid disease that may exacerbate the patient's underlying medical condition. For unclear reasons, sick patients older than 65 years who are taking other medications for a variety of comorbidities in addition to LT4 require lower doses of LT4 to normalize their serum TSH than do healthy controls of a similar age who taking only LT4. The difference in LT4 dose requirement persisted even after accounting for body weight. As other examples of medical conditions, patients with glomerular disease may require higher LT4 doses at times when their urinary protein losses are greatest,[74] and those with cirrhosis may also have an increased requirement for LT4, possibly because of increased levels of thyroxine-binding globulin.

Hospitalized Patients. When patients with hypothyroidism are hospitalized, their LT4 therapy should continue uninterrupted. If patients are unable to take their LT4 by mouth, it should be provided by other enteral routes such as via feeding tubes or the intravenous route, as appropriate. However, in a review of LT4 replacement therapy in an intensive care unit, it was found that 17% did not have their LT4 prescribed for more than 7 days, and 21% did not have their LT4 administered when enteral feeding was instituted.[75] Patients with TSH levels either above or below the reference range had longer median hospital lengths of stay (22 days) than those with normal TSH values (15 days).[75]

Coexistent Adrenal Insufficiency. If a patient has both hypothyroidism and suspected or documented adrenal insufficiency, cortisol replacement should be started concurrently with LT4 to avoid restoration of normal renal function increasing cortisol disposal, or normalization of metabolic rate increasing the requirement for cortisol, and thus precipitating an adrenal crisis.[7]

Subclinical Hypothyroidism. SCH is the one of the most prevalent thyroid diseases in developed countries, with a reported overall prevalence rate of 4.3% in a study of 17,353 individuals in the United States.[14] This prevalence was higher, at 9%, when individuals attending a health fair in the United States were studied.[58] Other studies of the general population reported prevalence rates of 4.9% and 3% in women and men, respectively, in the Netherlands, 7.5% and 2.8% in women and men respectively, in the United Kingdom, and 11% and 7.3% in women and men, respectively, in China.[13] However, different prevalence rates can be observed depending on the specific subpopulation studied. For example, when examining individuals over 60 to 65 years of age, the prevalences for women and men, respectively, were 7.1% and 2.7% in the United States, 11.6% and 2.9% in the United Kingdom, and 6.7% and 6.1% in Brazil.[13]

Each of the studies cited earlier, as well as other studies examining the prevalence of SCH, used a variety of different upper limits of normal for the TSH reference interval that was used to define SCH. Arguments have been made both in favor of lowering the upper end of the reference interval and in favor of maintaining it. The proponents of lowering the upper limit of the normal TSH range suggest that patients may have mild symptoms and abnormalities in lipids and cardiovascular function that can be improved with LT4 therapy. The concern would be labeling a larger population with having SCH, with treatment potentially being undertaken, without proven benefits of lowering TSH values that fall within this range. Indeed, it has been suggested that treatment decisions should not be guided so much by reference intervals, but by data showing benefit of treatment for particular degrees of TSH elevation. Moreover, reference intervals themselves may be better defined by the risk of disease rather than on population-based ranges.

There is an ongoing debate regarding the risks and benefits of treating SCH.[33] Many reviews regarding SCH conclude that there are less adverse consequences of mild SCH, compared with greater degrees of

SCH, in most populations, and that this is particularly true in specific populations such as the elderly.[76] This discussion has to be qualified with a consideration of whether specific populations can be defined as having SCH if a TSH reference interval that is derived from that particular population has not been used. For example, does a 75-year-old with a persistent TSH value of 5.5 mIU/L have SCH? This TSH value may well fall within the normal range if an age-adjusted reference interval is employed. Does a 25-year-old African American presenting with a TSH of 4.9 mIU/L not have SCH, when the reference intervals specific to his/her race and age are considered? This TSH value may be above the 97.5th percentile when race-adjusted reference ranges are employed.[77] Formulae for adjusting the TSH reference interval for age, ethnicity, and sex within the US population have been devised.[78] However, not all experts believe that there is a need for specific reference intervals for these subpopulations.

Even when there is agreement about the existence of SCH, benefits of treating generally have not been shown, except possibly in specific age groups.[79] On the other hand, there are some preliminary data that even serum TSH values that fall within the upper end of the TSH reference interval are associated with adverse outcomes.[43] A metaanalysis studied the risk of developing adverse outcomes in individuals with serum TSH values in the upper end of the normal reference range compared with the lower end of the range. Cardiovascular, metabolic, and skeletal outcomes were examined. The odds ratio for developing adverse cardiovascular and metabolic outcomes was significant at 1.21 (95% CI: 1.15–1.27) and 1.37 (95% CI: 1.27–1.48), respectively, whereas the odds ratio for adverse skeletal outcomes was significantly reduced at 0.55 (95% CI: 0.41–0.72).[43] Should this be confirmed, this might suggest that trials of treatment of SCH should enroll patients with even milder degrees of TSH elevation to better determine the risks and benefits of such treatment. A recent clinical practice guideline suggested that treatment of SCH should not be considered unless the TSH is above 20 mIU/L, except in certain subgroups.[80] This conclusion was reached despite the fact that only two of the trials in their associated metanalysis included patients with TSH values above 10 mIU/L. An alternative approach is to carefully consider the clinical context when deciding whether treatment of SCH is of benefit.[81]

Two recent studies have addressed the effect of LT4 on hypothyroid symptoms in older patients with SCH. Those over 65 years of age were studied in the TRUST trial,[82] and individuals over 80 years of age were studied in the IEMO80-plus Thyroid Trial.[83] Both of these trials enrolled patients with persistent TSH elevations of over 4.6 mIU/L. In the TRUST trial the mean TSH values at enrollment were 6.41 and 6.38 mIU/L, with declines to 3.63 and 5.48 mIU/L, in the LT4 group and the placebo group, respectively. In the study of those over 80 years (which included some individuals from the IEMO80-plus Thyroid Trial and some from the TRUST trial), the TSH values at enrollment were 6.50 and 6.20 mIU/L, with reduction to 3.69 and 5.49 mIU/L, in the LT4 and placebo groups, respectively. Neither of these trials showed any difference in their primary outcomes of hypothyroid symptoms or tiredness at 1 year. There was no effect of LT4 on secondary outcomes either. One could speculate that these trials would potentially have had different results if the TSH reference interval used was age-adjusted and resulted in a different definition of SCH, with a higher TSH value such as greater than 7 to 10 mIU/L being used for enrollment. Of note, a recent survey of clinicians found that 11% to 29% of those responding to the survey would treat a 80-year-old patient with tiredness and a TSH of 6.5 to 6.8 mIU/L with LT4.[84]

Myxedema Coma. Severe hypothyroidism can culminate in myxedema coma, a life-threatening condition characterized by hypothermia, bradycardia, hypotension, altered mental status, and multisystem organ failure. Risk factors include advanced age, poor access to healthcare, and other underlying major organ system diseases. Patients may present more frequently in the winter months, and most patients have severe and longstanding thyroid hormone deficiency. Treatment should include T4 (1.6–1.8 mcg/kg/day, with or without a 200- to 500-mcg loading dose). The rationale for the loading dose is to reoccupy the empty binding sites on thyroxine-binding globulin, so that administered LT4 can contribute to raising FT4 levels. Some experts advocate coadministration of LT3 in divided doses to compensate for impaired conversion of T4 to T3. No controlled trials have been performed to evaluate the relative benefits and risks of these different approaches. Glucocorticoids should be administered in stress doses until the results of a cosyntropin stimulation test performed to check for evidence of concomitant adrenal insufficiency are available. Care should be taken to avoid exposure to potent sedative or analgesic agents that may exacerbate altered mental status. Hypothermia should be treated with external warming to reduce the risk of circulatory collapse.

KEY POINTS: Levothyroxine Therapy

- Hypothyroidism generally requires life-long therapy with thyroid hormone replacement.
- There are well established protocols for initiation of levothyroxine therapy
- Levothyroxine therapy must be continually monitored as dose requirements may change with changes in a patient's physiological and medical situation.
- Both overtreatment and undertreatment of hypothyroidism can have adverse effects and monitoring is necessary to maintain euthyroidism.
- Specific treatment goals may need to be considered for specific patient populations.
- The majority of patients are believed to feel well while taking levothyroxine.
- A subset of patients do not feel well while taking levothyroxine, despite the best attempts to optimize therapy.

Therapy Other Than Levothyroxine

The standard of care therapy for hypothyroidism is LT4. The majority of patients, when they are treated to achieve a normal TSH, feel well while taking LT4. However, there are a subset of patients who do not feel fully restored to health and report reduced quality of life despite being biochemically euthyroid. This has led to studies to try and understand the underpinning of this reduced quality of life and also to investigate whether alternative therapies for hypothyroidism might yield greater levels of satisfaction.

Residual Symptoms While Taking Levothyroxine and Potential Underpinnings. Studies that have assessed well-being using the thyroid symptom questionnaire identified dissatisfaction in both the patients treated for hypothyroidism and also in age- and sex-matched patients without hypothyroidism. Approximately 14% more patients with hypothyroidism were dissatisfied compared with the control group.[85] The hypothyroid group did have more coexistent medical conditions, but the difference between the groups remained significant even after adjusting for these. Another study, in which subjects were recruited by letter and then subsequently took part in cognitive testing and completed questionnaires assessing well-being, also showed lower scores in both these areas in the euthyroid patients taking LT4 compared with standard reference values.[86]

Several factors have been proposed as contributing to the decreased quality of life in patients who are apparently euthyroid. These factors include failure to optimize serum TSH, coexistent medical conditions, low serum T3 levels during therapy, the presence of deiodinase or thyroid hormone transporter polymorphisms, and the presence of TPO Abs.[87] With respect to fine-tuning the TSH value in treated patients, most studies do not show improvement in patients' symptoms with lower TSH values. For example, a recent trial in which patients were randomly assigned to receive LT4 doses that resulted in three different ranges of TSH values showed that these different TSH targets had no effect on quality of life, mood, or cognition.[88] Patients with hypothyroidism do appear to have more chronic medical conditions than other populations,[89] but whether this accounts for their decreased quality of life is not clear.

LT4 therapy is associated with steady serum levels of T3 but is also associated with a higher T4/T3 ratio than is seen in endogenous euthyroidism. Many studies have examined the T3 levels achieved during LT4 monotherapy. These studies have had different methodology, including with respect to the group used as a comparator. In a study using patients as their own controls, T3 levels were better maintained.[53] However, most of these studies show that T3 levels are lower in a proportion of LT4-treated patients[7] and may even be below the T3 reference range in some studies.[90] In a small study of thyroidectomized patients, lower T3 levels were associated with being either homozygous or heterozygous for the Thr92Ala polymorphism of the type 2 deiodinase.[91] There are some limited data about the effect of type 2 deiodinase polymorphism status on either response to LT4 therapy or preference for combination therapy. One study performed a retrospective analysis of data from a study of combination therapy by Saravanan et al.[92] Participants underwent genotyping for the presence of the mutation encoding the Thr92Ala polymorphism and their scores on the General Health Questionnaire, both while taking LT4 and while taking combined LT4/LT3, were analyzed according to their polymorphism status. Ala/Ala homozygotes had worse General Health Questionnaire scores while taking LT4.[93] Moreover, they also had a better response to combination therapy based on their General Health Questionnaire scores.[93] Different TSH values could not be implicated, as TSH values did not differ between patients with the same genotype receiving combination therapy or monotherapy with LT4. However, other studies have not shown any association between scores of quality of life and cognition in LT4-treated patients according to their Thr92Ala status.[94,95] One small study found that patients with both the Thr92Ala polymorphism and a polymorphism in one of the thyroid hormone transporters preferred combination therapy with both LT4 and LT3.[96] There are data suggesting that the presence of TPO Abs, even in patients who have maintained endogenous euthyroidism, may be associated with more symptoms than are reported by euthyroid patients without thyroid autoimmunity. One study found more symptoms and lower quality of life in those with elevated titers of thyroid peroxidase antibodies, whereas another study reported more depression.

Combination Therapy With Levothyroxine and Liothyronine

Synthetic Combination Therapy. A relative T3 deficiency in those being treated with traditional LT4 monotherapy in the setting of some patient dissatisfaction with this therapy may prompt consideration of combination therapy with both LT4 and liothyronine (LT3). If the intention were to replicate the molar ratio of T4:T3 achieved by endogenous thyroid functioning in humans, the prescribed ratio would be approximately 14:1 to 15:1.[7] Thus, this would be best achieved using synthetic LT3, with adjustment of the LT3 dose by the prescribing physician. However, it is not well-understood what parameters should be used to make adjustments, given the short half-life of LT3.

Fourteen randomized trials examining the issue of combination therapy for patients with hypothyroidism have been performed.[7,97] Following an initial study in 1999, 12 additional studies were performed between 2002 and 2010, with a subsequent study in 2016. These studies had variable designs with respect to the outcomes studied, the use of crossover or parallel groups, blinding methodology, and the ratio of T4 to T3 employed. However, autoimmune hypothyroidism was the predominant diagnosis in most studies. With some exceptions (see later), these studies failed to demonstrate a benefit of LT3 combination therapy. Four metaanalyses or reviews that incorporated the trials completed at the time of the analysis also concluded that there is no advantage to combination therapy.[7] However, these metaanalyses were made difficult by the heterogeneity of the trials with respect to causes of hypothyroidism, different dosing regimens, different outcome measures, different duration of treatment, and different TSH and T3 levels achieved in the combination therapy groups. Other design issues included nonvalidated outcome measures, carryover effects in some studies, overtreatment in some studies, and failure to study therapy in men and the elderly. Recent reviews and guidelines have stressed the need for larger, better-designed studies of longer duration.[7,98]

Health-related quality of life or mood was studied in 13 trials, with very heterogeneous results.[7] There was superiority of combination therapy on multiple measures in two trials, one by Bunevicius et al.[99] and one by Nygaard et al.[100] These two trials included patients with thyroid cancer and low TSH values, and used a large single dose of LT3 (20 mcg), respectively. Superiority of combination therapy for a minority of measures was seen in two trials.[92,101] In one of these trials the benefit was seen at 3 months, but was no longer seen at 12 months.[92] Of note, the latter is the only combination therapy study of 12 months' duration, with the next longest trials being 4 months and 6 months in duration. The remaining nine trials did not show any superiority of combination therapy with respect to improving quality of life.

Neurocognitive functioning was studied in ten trials, again with heterogeneous results.[7] Superiority of combination therapy on multiple measures was found in one trial.[99] Superiority of combination therapy for a minority of measures was also found in one trial.[102] The remaining eight trials did not show a superior effect of combination therapy on neurocognitive functioning. An example of a negative trial with respect to both quality of life and cognitive functioning is a 4-month study by Clyde et al.[103] In this study, LT4 alone was compared with combination therapy by substituting 50 mcg of LT4 with 7.5 mcg of LT3. This study demonstrated no beneficial changes in body weight, serum lipid levels, hypothyroid symptoms as measured by a health-related quality of life questionnaire, and standard measures of cognitive performance.

Patient preference has been studied in five blinded crossover design trials and two blinded, parallel design trials of combination therapy.[7] With respect to the crossover design trials, the combination therapy was preferred in four trials, which, when combined, total 128 patients.[99,100,102,104] Another trial of 101 patients did not demonstrate a preference for combination therapy.[105] Of the two parallel design trials, there was a preference for combination therapy in one trial of 130 patients[106] and no preference for combination therapy in another trial of 573 patients.[92] The former trial was characterized by some degree of overtreatment, and preference for combination therapy was associated with weight loss. The latter trial was the largest and longest-duration trial of combination therapy conducted thus far.

Natural Combination Therapy. There is considerable patient interest in "natural" combination therapy in the form of DTE. One small trial of DTE randomized patients to either LT4 or DTE and then switched them to the other therapy after 16 weeks, for a further 16 weeks of therapy.[107] During the DTE treatment arm, patients had significantly higher serum levels of T3 and lower levels of FT4. Multiple different parameters of quality of life were assessed during the trial, and these parameters did not differ between the two groups. However, 49% of patients preferred the DTE, compared with 19% preferring LT4 and 33% having no preference.[107] Preference for DTE was found to be associated with weight loss. A recent online survey of patients with hypothyroidism found that those responding to the survey had a higher level of satisfaction with DTE than those receiving other therapies.[108] Reported satisfaction level on a scale of 1 to 10 was 7 (interquartile range 4, 8) for DTE, compared with 6 (3, 8) for synthetic combination therapy with LT4 and LT3 and 5 (3, 7) for LT4 alone. These data need to be evaluated with the self-selected nature of the respondents being considered.

Monotherapy With Liothyronine. Monotherapy with LT3 has rarely been used, in part because of the need to take LT3 multiple times a day to maintain a reasonably stable TSH. Preference for LT3 alone compared with LT4 alone has not been studied in a controlled fashion.

Reduction of Thyroid Peroxidase Antibodies. Whether TPO Abs themselves affect patient quality of life, including in the setting of a normal TSH, has been investigated. In a recent randomized trial, patients with continued symptoms while receiving LT4, who also had significantly elevated TPO Ab titers of greater than 1000 IU/mL (median 2232 IU/mL), were randomized to thyroidectomy or continued medical management. In those who underwent thyroidectomy, TPO Abs declined to a median of 152 IU/mL. Health-related quality of life and fatigue improved in the thyroidectomized patients and was sustained at 12 to 18 months.[109] There was no sham-thyroidectomized group. An earlier nonrandomized study of thyroidectomy for hypothyroid symptoms did not identify a similar benefit for those without TPO Abs.[110] Other therapies tested as a means of reducing TPO Abs, such as specific diets, have not been sufficiently studied.

KEY POINTS: Therapy Other Than Levothyroxine

- If patients have unresolved symptoms with levothyroxine therapy, potential causes of these symptoms should be fully investigated.
- If no cause of patient dissatisfaction is identified, a trial of personalized combination therapy with addition of liothyronine can be contemplated, and can be continued as long as patient benefit and safety is maintained.
- Trials of combination therapy with levothyroxine and liothyronine have not shown patient benefit, but these trials were largely underpowered, of short duration and used once daily liothyronine dosing.
- Future combination therapy trials that address some of the weaknesses of prior trials, and also utilize a sustained release liothyronine preparation, may show different results.
- A future goal is to prevent the cascade of events that leads to autoimmune destruction of thyroid tissue.

SUMMARY AND AREAS OF FUTURE RESEARCH

Despite the significant advances that have been made in our understanding of thyroid hormone therapy, some of these insights have not been easy to translate into practical applications. Additionally, some of the challenges that continue to face physicians treating patients with hypothyroidism concern basic fundamentals. With respect to the former issue, although we recognize that LT4 does not recapitulate all aspects of normal thyroid physiology, we still do not have a "physiologic" replacement therapy. As an example of the latter issue, a significant number of patients with hypothyroidism are either undertreated or overtreated. This is a complex problem, as out-of-range TSH values may be attributed to multiple factors as diverse as confounding medications, interfering conditions, or intrinsic patient variables. The patient variables may be as basic as adhering to prescribed therapy. Such problems, with multiple etiologies, may require creative and sustained efforts in order for them to be addressed.

These challenges are also combined with exciting opportunities for understanding the nuances of fully reversing the consequences of hypothyroidism. Advances in our understanding of genetic diversity in the function of deiodinases, and possibly thyroid hormone transporters, may ultimately enable us to provide therapy tailored to individual patients. Future prospects include understanding the genetic underpinning of thyroid hormone delivery to tissues, developing more physiologic, sustained release or combination thyroid hormone therapies incorporating T3, and facilitating achievement of adequate thyroid hormone levels in all tissues. Although so far only shown in animal models, another hope for the future is the regeneration of functional thyroid follicles from embryonic or pluripotent stem cells. Such cells, once differentiated into thyroid follicular cells, have been shown to be capable of expressing thyroid-specific genes, responding to TSH stimulation, actively transporting iodine, forming three-dimensional follicles, and expressing thyroglobulin. Should such advances be extended to humans, this would not only provide the opportunity for a better understanding of thyroid physiology and disease but may also pave the way for regenerating the full hormonal profile of a normally functioning thyroid gland and thereby restoring euthyroidism in its entirety.

THYROID DISEASE AND FERTILITY

Adequate thyroid hormone availability is important for female reproduction. Thyroid hormone regulates key processes in female reproduction, both indirectly and directly. Various studies have shown that thyroid disease, including subclinical thyroid dysfunction and thyroid autoimmunity, is associated with infertility and suboptimal fertility treatment outcomes. However, the majority of these studies have been limited by their retrospective nature, small sample size, or selected population (typically women undergoing assisted reproduction). The overrepresentation of studies in subfertile women necessitates generalization and extrapolation of results for decision-making in fertile women. Furthermore, clinical decision-making strategies are also based on our understanding of thyroid physiology and pathophysiology, as well as efforts aimed at restoring homeostasis. Diagnosis and interpretation of thyroid function test abnormalities should not only focus on the preconception period, but also anticipate effects on gestation and fetal development.

Epidemiology

Thyroid disorders are relatively common among women of reproductive age because of the sex and age distributions of Hashimoto thyroiditis and Graves hyperthyroidism, as well as the increased detection of subclinical disease entities because of preconception screening. Data on the true prevalence of thyroid disease and thyroid autoimmunity in women of reproductive age are scarce because the majority of studies focus only on subclinical disease or thyroid autoimmunity in populations of subfertile or infertile (used synonymously hereafter) women. Furthermore, instead of normal nonpregnancy reference ranges, many studies have used an upper limit for thyroid-stimulating hormone (TSH) of 2.50 mIU/L, which is an incorrect cutoff that leads to considerable overdiagnosis and overtreatment in up to 20% of otherwise healthy women. Of women referred to a fertility center or with a previous miscarriage, almost 5% will have a thyroid function test abnormality. Overt hypothyroidism or overt hyperthyroidism occur only in approximately 0.2% to 0.3%, whereas subclinical hypothyroidism occurs in approximately 2.4% and subclinical hyperthyroidism in approximately 1.3% of women. Furthermore, among women referred to a fertility center and/or with a previous miscarriage, 9.5% to 12.3% are thyroid peroxidase antibody (TPOAb)–positive, which is probably slightly higher than in otherwise healthy pregnant women (mean 7.5%; range 4.7%–15.0%).[1-3] Similar to the general population, risk factors for thyroid disease and autoimmunity in women of reproductive age include ethnicity (e.g., a higher risk of Hashimoto thyroiditis in Whites but a higher risk of Graves hyperthyroidism in Black and Asian women), increased age, the presence of other autoimmune disorders, smoking (Graves hyperthyroidism), and insufficient or excessive iodine intakes.

Physiology

Thyroid hormone can affect female reproduction either directly, through regulation of key cellular processes, or indirectly, through interference with other hormonal axes. Thyroid hormone receptors are abundantly present throughout the human female reproductive tract, including in granulosa cells and oocytes.[4-8] Preclinical studies show that thyroid hormone regulates the stimulatory effects of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) on granulosa cells, follicular growth, and oocyte development.[9,10] These effects are mediated via thyroid hormone regulation of 3,β-hydroxysteroid dehydrogenase (the enzyme that facilitates the final step in progesterone formation), aromatase (the enzyme that facilitates the final step in estradiol formation), and LH/human chorionic gonadotropin (hCG) receptor expression. Indirect effects of thyroid hormone on female reproduction can be extrapolated from clinical observations of menstrual and ovulatory disturbances in both hypo- and hyperthyroidism. Hypothyroidism leads to a blunted FSH and LH response to gonadotropin-releasing hormone (GnRH), hyperprolactinemia, and lower sex hormone–binding globulin (SHBG) and estradiol concentrations, the clinical consequences of which can be reversed by reestablishing euthyroidism.[11] On the other hand, hyperthyroidism is associated with a greater LH and FSH response to GnRH, higher SHBG and estradiol concentrations, and high testosterone and androstenedione concentrations.[11] Although it is likely that similar physiological changes occur in subclinical thyroid disease, studies remain scarce.

Physiology During Assisted Reproduction Technology

Thyroid function test results remain stable throughout a normal menstrual cycle but can change during controlled ovarian hyperstimulation (COH; as employed for assisted reproduction). The rapid increase in estradiol during COH increases thyroxine-binding globulin (TBG) concentrations and type 3 deiodinase (D3) gene transcription.[12] Therefore, an increase in thyroid hormone production is required to ensure adequate thyroid hormone availability (Fig. 75.1). hCG administration may slightly increase free thyroxine (FT4) concentrations (see Fig. 75.1). The increased demand for thyroid hormone during COH is also demonstrated by the changes in TSH and FT4 concentrations in women treated with a fixed dose of levothyroxine. Furthermore, this is supported by data from TPOAb-positive women, who likely have a reduced thyroid functional capacity, as TPOAb-positive women typically exhibit a considerable and sustained increase in TSH following COH (Fig. 75.2).

Clinical Outcomes and Management

Data on the association of preconception thyroid function with fertility or pregnancy outcomes in apparently healthy women are sparse, of low quality, and conflicting. For example, a large population-based study[13] performed in China showed that women with a high-normal or increased preconception TSH had a slightly higher risk of abortion and preterm birth, but this was not replicated in a cohort of healthy Australian women.[14] There is a clear indication to treat preconception overt thyroid disease from the view of fertility, conception, and pregnancy. Women with adequately treated preconception hypothyroidism have a similar risk of adverse pregnancy outcomes as euthyroid women. However, suboptimal levothyroxine treatment in women with overt hypothyroidism during early pregnancy is associated with a 1.8- to 4-fold higher risk of miscarriage[15] and slightly higher risks of other adverse pregnancy outcomes such as preterm birth and preeclampsia. Overt hypothyroidism requires thyroid hormone replacement with a preconception or pre-assisted reproduction technology (ART) target TSH of less than 2.5 mIU/L. Women should be counseled to contact their healthcare provider before starting ART or at the time of a positive pregnancy test so that their thyroid function can be checked and the levothyroxine dosage can be increased by roughly 30% as soon as they are pregnant. Any thyroid hormone formulations containing liothyronine should be avoided preconception and during pregnancy, because triiodothyronine (T3) is unlikely to reach the fetal brain, and it can decrease maternal serum thyroxine (T4) concentrations. For women with hyperthyroidism, especially Graves disease, a permanent preconception treatment modality is recommended either before ART or pregnancy (see later).

In euthyroid TPOAb-positive women, clinical follow-up throughout COH and gestation is advised, owing to the high risk of thyroid function deterioration to the point of a treatment indication during pregnancy or during COH (Fig. 75.2). Because of a lack of high-quality data, the decision about whether or not to start levothyroxine treatment for TPOAb-negative subclinical hypothyroidism should be tailored to each specific patient and should take into account data from studies in women undergoing infertility treatment (see later), as well as other risk factors for adverse outcomes such as a prior history of miscarriage or preterm birth, age, body mass index (BMI), and comorbidities (Fig. 75.3).

The majority of studies thus far have focused on the associations of preconception subclinical hypothyroidism and thyroid autoimmunity (mainly TPOAb positivity) in infertile women with early *in vitro* fertilization (IVF) outcomes, miscarriage, and live birth rates. In these heterogeneous study populations, it remains difficult to establish whether subclinical hypothyroidism is a risk factor for adverse outcomes in women undergoing ART.[16] A metaanalysis of three small randomized controlled trials (RCTs) has indicated that levothyroxine treatment in women with subclinical hypothyroidism may increase the number of fertilized oocytes, and reduce the relative risk of miscarriages by 31%.[17]

Data regarding thyroid autoimmunity and the risk of adverse ART outcomes are more consistent. TPOAb positivity is a more specific risk factor for adverse fertility or pregnancy outcomes than thyroglobulin antibody (TgAb) positivity. Although TPOAb positivity is

not associated with early IVF outcomes such as oocyte quality/yield or implantation rate, observational studies show that TPOAb positivity is associated with an approximately 44% higher relative risk of miscarriage and, consequently, with a 35% lower relative chance of live birth.[18] Two randomized trials have indicated that, for euthyroid TPOAb-positive patients with a prior miscarriage or undergoing fertility treatment, levothyroxine treatment has no beneficial effects. One randomized trial compared 226 euthyroid TPOAb-positive women who received levothyroxine (25–50 µg/day, depending on their TSH concentration) to an equally sized control group and found similar rates of miscarriage (10.6% vs. 10.3%) and live births (32.3% vs. 31.7%).[3] Interestingly, subanalyses indicated a beneficial effect of levothyroxine treatment on the risk of miscarriage specifically in cases of a female cause of infertility, as opposed to a male or idiopathic cause of infertility (levothyroxine 7.3% vs. control 16.1%), although the study was not powered to show statistical significance for those analyses.[3] Another randomized trial compared 476 euthyroid TPOAb-positive women who received a fixed TSH dosage of 50 μg/day to an equally sized control group and found similar rates of miscarriage (28.2% vs. 29.6%) and live births (37.4% vs. 37.9%).[19] These studies provide good evidence for a lack of benefit from levothyroxine treatment for euthyroid TPOAb-positive women, even if the TSH is above 2.5 mIU/L. Nonetheless, TPOAb positivity is an indication for follow-up thyroid function tests during COH, pregnancy, and postpartum.

TPOAb positivity with a preconception TSH above the reference range is considered to be an indication to start levothyroxine treatment, particularly when other risk factors for adverse ART or pregnancy outcomes are present, including a prior history of miscarriage or failed ART and age greater than 35 years (Fig. 75.3). The main argument for this is that these women are highly unlikely to normalize their thyroid function during COH or pregnancy and will thus eventually have a treatment indication. If levothyroxine therapy is elected, treatment should start with a low dose (25–50 μg/day), with subsequent dose titration to target a serum TSH of less than 2.5 mIU/L.

KEY POINTS

- Thyroid dysfunction and thyroid autoimmunity are common among women referred for fertility treatment. Overt thyroid dysfunction should be screened for and treated preconception in women with subfertility. Decisions about the treatment of subclinical hypothyroidism in the preconception setting must be individualized.

MATERNAL AND FETAL PHYSIOLOGY IN PREGNANCY

The maternal supply of thyroid hormone to the fetus, an increase in TBG concentrations under the influence of high maternal estrogen, an increase in renal iodine clearance, and the degradation of thyroid hormone by placental D3 together necessitate an increase in thyroid hormone production to ensure adequate availability for mother and fetus.[11] This increased demand for thyroid hormone production is normally met through additional thyroid stimulation by high concentrations of the pregnancy hormone hCG, a weak agonist of the TSH receptor (Fig. 75.4).[20] These pregnancy-specific changes and increased demand may expose preexisting mild thyroid dysfunction or cause new hypothyroidism.

Thyroid hormone is crucial for normal fetal brain development because it regulates the migration, proliferation, and differentiation of fetal neuronal cells, as well as synaptogenesis and myelination. In human fetuses, early neurogenesis begins at approximately 5 weeks postconception, and thyroid hormone receptors have been detected in the fetal brain at as early as 8 weeks' gestation. Because the fetal thyroid gland is not functionally mature before week 18 to 20 of pregnancy, the fetus largely depends on the supply of maternal T4 during the early stages of intrauterine brain development. Later in pregnancy, maternal T4 continues to contribute to fetal thyroid hormone availability (Fig. 75.4). Thyroid autoimmunity, generally reflected by TPOAb positivity, is the most important risk factor for thyroid dysfunction during pregnancy. Recent studies show that the thyroidal response to hCG stimulation is severely impaired in TPOAb-positive women, leading to a relative thyroid hormone shortfall during early pregnancy.[21]

KEY POINTS

- Maternal thyroid hormone synthesis normally increases by 50% in pregnancy. Maternal thyroid hormone is critical for fetal brain development during early gestation, before the onset of fetal thyroid function.

THYROID FUNCTION TESTS IN PREGNANCY

The major changes in thyroid physiology necessitate the use of pregnancy-specific reference ranges to diagnose thyroid disease during gestation. Although many centers previously used fixed upper limits for TSH of 2.5 mIU/L in the first trimester and 3.0 mIU/L in the second or third trimester, it has been shown that these cutoffs are too low and cause considerable overdiagnosis. Ideally, a stepwise approach should be used to define the optimal reference range for each specific institution. Lab-specific, gestational age-specific TSH and FT4 reference ranges are the gold standard. A lab-specific reference range for TSH and FT4 can be calculated as the 2.5th to 97.5th percentiles for a group of at least 400 women who are free of thyroid function-interfering factors (major disease, severe iodine deficiency, TPOAb positivity, thyroid [interfering] drug use, higher physiological hCG [e.g., twin pregnancies and/or IVF treatment]).[22] If it is not possible to obtain lab-specific reference ranges, reference ranges from other centers using the same assay and with a similar patient population can be adopted. Finally, if proper reference ranges cannot be obtained via either of the previous steps, a fixed upper limit for TSH of 4.0 mIU/L may be used.[23]

FT4 is required to distinguish between overt and subclinical thyroid disease. However, it is not possible to identify an evidence-based fixed lower limit for FT4, because published reference ranges differ widely and are highly assay-specific. Therefore, the lower range for FT4 is best defined using a laboratory-specific or "adopted" reference range approach. Commonly used FT4 immunoassays have been reported to be inaccurate because of a shift in thyroid hormone-binding proteins during pregnancy.[24] This shift affects FT4 measurements during the late second and third trimester and is therefore less likely to affect thyroid function tests in the first half of pregnancy. Furthermore, because between-assay correlation for FT4 concentrations is very high,[25-27] commercial assays can be used to adequately identify women with abnormal FT4 if pregnancy-specific and assay-specific reference ranges are used, as shown in metaanalyses.[28,29] Total T4 is a suboptimal marker for thyroid function during pregnancy, as it represents a very crude estimate of the fraction of available thyroid hormone, is highly dependent on changes in TBG, and there is no association with adverse outcomes. For the same reason, T3 concentrations are not used for defining abnormal thyroid function during pregnancy, and the general quality of free T3 assays limits their use both outside of and during pregnancy.

KEY POINTS

- Thyroid function shifts over the course of gestation. Assay- and gestational age-specific reference ranges for TSH and free T4 levels should be used when available.

HYPERTHYROIDISM IN PREGNANCY

In otherwise healthy women, a biochemical diagnosis of overt hyperthyroidism can be made in 0.7% to 0.9%, and another 1.0% to 2.1% of women can be diagnosed with subclinical hyperthyroidism.[30] However, from a clinical perspective, two major subtypes of overt

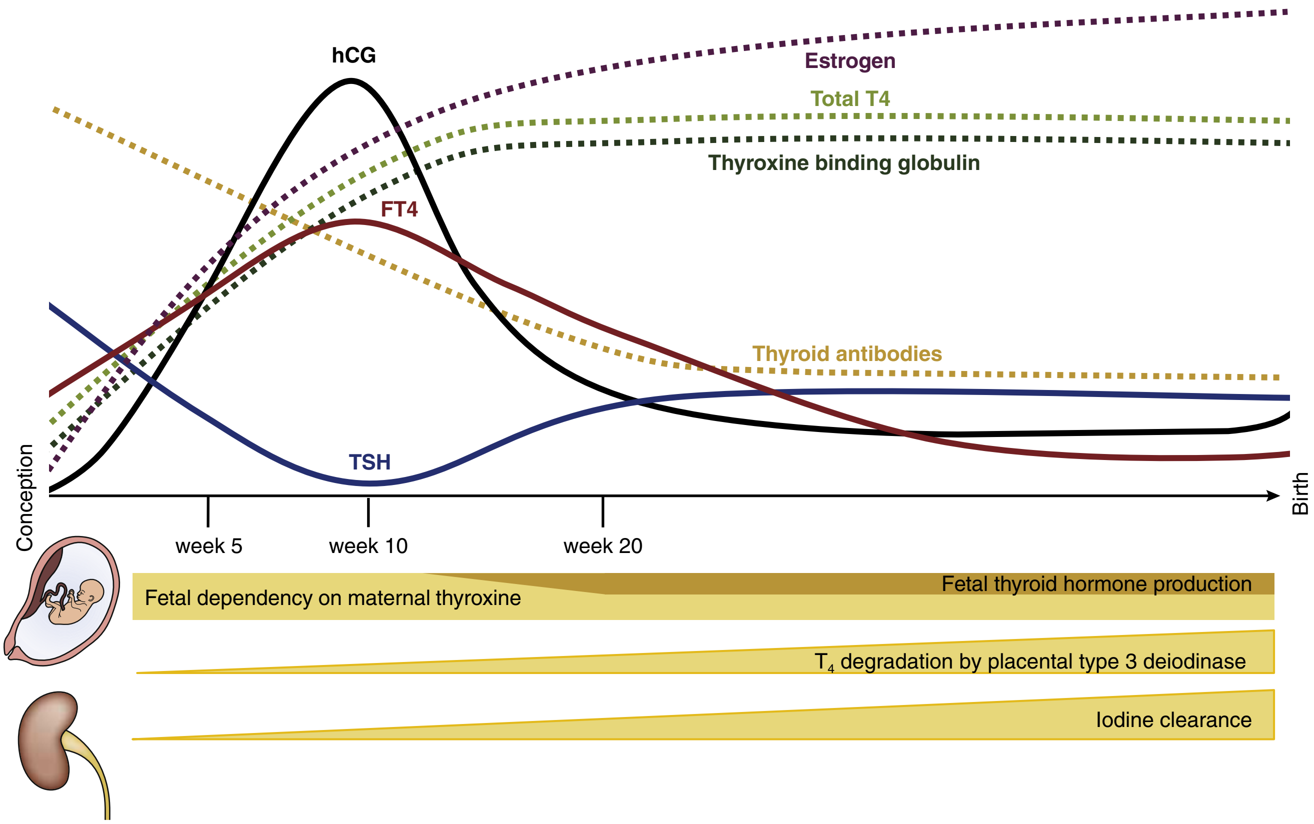

Fig. 75.4 **Thyroid physiology throughout pregnancy.** *TSH,* Thyroid-stimulating hormone; *hCG,* human chorionic gonadotropin; *FT4,* free thyroxine.

hyperthyroidism should be distinguished. First, the majority of women with gestational hyperthyroidism will present with a physiological form of transient biochemical hyperthyroidism (also referred to as gestational transient thyrotoxicosis). This is caused by high hCG concentrations, which typically peak between 8 to 12 weeks of pregnancy and are higher in IVF and twin pregnancies (Fig. 75.4). Most of these women have no or mild (transient) thyrotoxic symptoms and rarely require symptomatic treatment (i.e., propranolol). Trophoblastic diseases, partial and complete hydatidiform moles, and choriocarcinoma are other rare causes of hCG-mediated (but pathological) hyperthyroidism in pregnancy. Non-hCG-mediated hyperthyroidism, the second major type of overt hyperthyroidism in pregnancy, is caused by Graves disease or, less commonly, autonomous thyroid hormone production (toxic adenoma or multinodular toxic goiter). Non-hCG-mediated hyperthyroidism during pregnancy is rare and can be further categorized as preexisting Graves disease (estimated prevalence 0.5%), new-onset Graves disease (0.05%), and autonomous thyroid hormone production (0.1%).[31,32] When untreated, the vast majority of women with Graves disease will present with overt biochemical abnormalities and thyrotoxic symptoms. Overt hyperthyroidism from Graves disease is associated with a high risk of adverse outcomes such as preeclampsia, preterm birth, low birth weight, and maternal heart failure.[31,33] The clinical presentation of women with hyperthyroidism because of a toxic nodule or toxic multinodular goiter is more heterogeneous. In some cases, the additional hCG stimulation of pregnancy causes only transient hyperthyroidism, while preconception hyperthyroidism because of nodular disease may be more severe and in some cases necessitate treatment with antithyroid drugs, surgery, or radioablation therapy.

Diagnosis

Although some clinical clues, including the personal and family past medical history, preconception onset of symptoms, goiter, or ophthalmopathy, can raise suspicion for Graves hyperthyroidism, biochemical evaluation is the key to diagnosis (Fig. 75.5). Typically, Graves hyperthyroidism in pregnancy presents with a FT4 concentration greater than 1.5 times the upper limit of normal and relatively high T3 concentrations but, most importantly, markers of autoimmunity in the form of positive serum thyroid-stimulating immunoglobulin or TSH receptor antibody (TRAb). Because new-onset Graves disease during pregnancy is very rare, some physicians prefer to perform a targeted approach to TRAb testing, while others prefer a universal testing approach in women with hyperthyroidism during pregnancy. In rare cases of a suspected nonpalpable toxic (T3-producing) adenoma, thyroid ultrasound may be useful, although there is a high baseline risk of thyroid incidentaloma of up to 33%.[34] Thyroid ultrasound cannot be used to distinguish physiological, hCG-mediated hyperthyroidism from Graves hyperthyroidism.

Treatment and Monitoring

Gestational thyrotoxicosis and subclinical hyperthyroidism typically do not require treatment. A conservative approach, for example monitoring thyroid function every 4 to 6 weeks until FT4 concentrations decrease, suffices for the vast majority of cases. Many women with gestational thyrotoxicosis have severe morning sickness or hyperemesis gravidarum and may need supportive care with antiemetics or intravenous hydration. For toxic adenomas and Graves disease, biochemical control of hyperthyroidism is essential to prevent adverse maternal, fetal, and neonatal complications. Maternal

FT4 concentrations should be used to monitor treatment, because TSH can remain suppressed and (F)T3 concentrations do not adequately reflect fetal thyroid hormone availability. The treatment target should be an FT4 concentration in the upper third of the reference range, because the fetal thyroid is more sensitive to antithyroid drugs (ATDs), and lower maternal FT4 concentrations are associated with a higher risk of fetal hypothyroidism (upper third: 10% vs. 36% for lower two-thirds).[43]

When hyperthyroidism is diagnosed preconception, various treatment modalities can be used to establish biochemical control. Of note, there is an important role for prepregnancy counseling and shared decision-making, because toxic adenomas and the vast majority of Graves disease complicating pregnancy will predate conception. One option that can be considered is radioactive iodine, which is contraindicated during pregnancy and lactation. When considered preconception, women should be counseled to avoid conception for 6 months post-radioactive iodine therapy because of risk of teratogenicity from the radiation and the need to establish euthyroidism on levothyroxine. TRAb titers typically increase for approximately 1 year following radioactive iodine administration,[35] and women with high baseline TRAb titers should be counseled that this may increase the risk for fetal and neonatal complications. Another option is thyroidectomy, which results in relatively swift biochemical control and normalization of serum TRAb concentrations but confers a risk of surgical complications and requires lifelong thyroid hormone therapy. Finally, treatment with ATDs is effective in establishing biochemical control and normalization of serum TRAb concentrations but, when used in the first trimester, is associated with an additional 3% to 5% absolute risk increase in fetal birth defects. That is in addition to the well-known, but very rare, side effects of hepatic failure for propylthiouracil (PTU) or agranulocytosis for both ATDs.[36-38] PTU is the preferred drug during organogenesis in the first trimester, because large population studies indicate that the use of PTU during early pregnancy is associated with a slightly lower risk of birth defects (absolute risk increase: 3% vs. 5% for methimazole [MMI]) but also less severe fetal anomalies as compared with MMI.[36,37,38]

To limit the potential adverse outcomes associated with ATDs, several pregnancy-specific ATD strategies can be applied. First, in women of childbearing age with hyperthyroidism, the options for definitive treatment and the patient's preference should be discussed preconception. Second, if the patient prefers ATDs or is already pregnant while on ATDs, so-called block and replace therapy (a high dose of ATD with levothyroxine titration) should be avoided, and therapy should consist of ATD monotherapy with titration to euthyroidism with the lowest possible dose of PTU. Women using MMI preconception who are likely to require continuing therapy during pregnancy (i.e., those with more severe disease) should be switched to PTU preconception. It remains unknown whether switching from MMI to PTU in the first trimester of pregnancy reduces the risk of fetal birth defects. Switching strategies increases the risk of biochemical uncontrolled disease, and the single study that compared women who switched from PTU to MMI in the first trimester with those who continued MMI therapy found no difference in the risk of fetal birth defects.[38] Owing to immune tolerance and the subsequent alterations in maternal immune response during pregnancy, the dose of ATDs should typically be reduced from the second half of pregnancy onwards, guided by maternal FT4 levels, to avoid overtreatment and fetal hypothyroidism.[39-40] Third, in women who are biochemically controlled with a stable low dose of MMI (5–10 mg) or PTU (100–200 mg) before pregnancy, the chance of relapse is lower than the overall 30% to 50% risk, and relapse would most likely occur after a few weeks to months.[41] Therefore, stopping ATD treatment immediately at the time of a positive pregnancy test and monitoring thyroid function every 2 weeks can be considered to prevent the risks related to ATD exposure.[23]

In women with a history of active Graves disease, measurement of TRAbs should be performed in early pregnancy (Fig. 75.5).

If biochemical control is not established before the second half of pregnancy, or if TRAbs are increased more than three times the upper limit of normal, additional maternal and fetal monitoring is required. Additional monitoring to determine the risk of hyperthyroidism (from maternal TRAb) or hypothyroidism (from ATD) in the fetus can start from midpregnancy (i.e., at 28, 32, and 36 weeks) via assessment of the fetal heart rate (normal <160/min), fetal growth, fetal thyroid size, and signs of increased or delayed bone maturation. Maternal thyroid function monitoring at the same time points is also informative, as the maternal thyroid function reflects fetal thyroid hormone availability.[42,43] For rare cases of uncontrollable Graves hyperthyroidism during pregnancy, treatment using high-dose potassium iodide, prednisolone, or thyroidectomy should be considered in the setting of a multidisciplinary team.[44]

Lactation

Both PTU and MMI are safe for use during breastfeeding, and thyroid function testing of infants is not required, as only a small fraction (<0.2%) of the maternal dosage will reach the breast milk.[45,46] The neonate depends on maternal iodine, but not thyroid hormone, transfer via breast milk. Nonetheless, maintaining maternal euthyroidism postdelivery remains important, as hypothyroidism can cause poor lactation. Although case reports have described measurable TRAb concentrations in breast milk, these are unlikely to cause neonatal Graves disease because these will be degraded in the gastrointestinal tract of the neonate.

KEY POINTS

- When hyperthyroidism occurs in early pregnancy, gestational transient thyrotoxicosis (which requires only monitoring and supportive care) must be differentiated from overt Graves hyperthyroidism (which requires treatment). Given the potential teratogenicity of anti-thyroid drugs, preconception counseling is essential for women with Graves disease. Treatment decisions in pregnancy must consider both maternal and fetal effects of therapy.

HYPOTHYROIDISM AND HYPOTHYROXINEMIA IN PREGNANCY

Overt Hypothyroidism

Overt maternal hypothyroidism (increased TSH with low FT4) during pregnancy occurs in roughly 0.5% of women. Thyroid autoimmunity and iodine deficiency (in some parts of the world) are the most important risk factors. Gestational overt hypothyroidism, as well as suboptimally treated preexisting overt hypothyroidism, are associated with a higher risk of adverse pregnancy complications, including miscarriage, premature delivery, low birth weight, miscarriage, and preeclampsia, as well as an up to 7-point lower child intelligence quotient (IQ).[15,47] Although randomized trials are unavailable for ethical reasons, in view of the detrimental effects of untreated overt hypothyroidism and evidence of a normalized risk of pregnancy complications in women with adequately treated hypothyroidism, there is general consensus that overt hypothyroidism during pregnancy should be treated as early as possible. Levothyroxine is the treatment of choice, with a target TSH of less than 2.5 mIU/L. For overt hypothyroidism, the levothyroxine dosage used outside of pregnancy (1.3–1.8 μg/kg/day) should be increased by approximately 30%–50% to meet the increased thyroid hormone demand of pregnancy.[48] To prevent overtreatment, the dose increase should be titrated, and thyroid function should be monitored every 4 to 6 weeks.

KEY POINTS

- Untreated overt hypothyroidism has adverse effects on pregnancy outcomes and fetal brain development. Most women will require increased levothyroxine doses in pregnancy, with close monitoring of serum TSH levels to achieve a goal TSH <2.5 mIU/L.

Subclinical Hypothyroidism

Subclinical hypothyroidism, defined as an elevated serum TSH in the setting of normal peripheral thyroid hormone levels, is relatively common in pregnancy. Prevalence estimates have varied based on the use of differing TSH thresholds for diagnosis, differences in the timing of thyroid function assessment across pregnancy cohorts, and regional variation in iodine intakes. A recent metaanalysis using the 97.5th percentile as the TSH upper limit estimated that 3.5% of pregnant women are subclinically hypothyroid.[30] In iodine-sufficient regions, subclinical hypothyroidism is most frequently caused by autoimmunity. Maternal subclinical hypothyroidism has been linked to preterm birth, placental abruption, pregnancy loss, small-for-gestational-age infants, low birth weight, and neonatal death.[2,49,50] Whether or not subclinical hypothyroidism in pregnancy requires treatment with levothyroxine remains controversial.

Multiple prospective observational studies have examined associations between subclinical hypothyroidism and adverse obstetric outcomes. In a systematic review that included 18 cohorts, maternal subclinical hypothyroidism was associated with increased risk for pregnancy loss (relative risk [RR] 2.01, 95% confidence interval [CI]: 1.66–2.44), premature rupture of membranes (RR 1.43, 95% CI: 1.04–1.95), placental abruption (RR 2.14, 95% CI: 1.23–3.70), and neonatal death (RR 2.58, 95% CI: 1.41–4.73) compared with euthyroidism.[49] An individual participant–level metaanalysis that included data from over 48,000 mother-child pairs concluded that maternal subclinical hypothyroidism is associated with increased risk for having a small-for-gestational-age infant (odds ratio [OR] 1.24, 95% CI: 1.04–1.48) and lower mean birth weight compared with euthyroidism.[50] Having both subclinical hypothyroidism and TPOAb positivity seems to confer greater risk for miscarriage and premature delivery than having either risk factor alone. A prospective cohort study in 3315 Chinese women found that women with both subclinical hypothyroidism and thyroid autoimmunity were at higher risk for miscarriage compared with euthyroid, antibody-negative women (OR 9.56, 95% CI: 3.76–24.28) than those with only subclinical hypothyroidism (OR 3.4, 95% CI: 1.62–7.15) or those with only thyroid autoimmunity (OR 2.71, 95% CI: 1.43–5.12).[51] Similarly, an individual participant–level metaanalysis including over 47,000 pregnant women demonstrated that the risk of preterm birth was higher for subclinically hypothyroid women than euthyroid women (OR 1.29, 95% CI: 1.01–1.64) and still higher (OR 1.55, 95% CI: 1.05–2.27) when both TPOAb positivity and TSH were present.[2] Overall, although individual observational cohorts have reported variable results, likely because of heterogeneity in the definition of subclinical hypothyroidism, adequacy of study power, timing of assessment in pregnancy, and whether or not TPOAb-positive women were excluded, a growing body of evidence from large studies demonstrates that maternal subclinical hypothyroidism, particularly in the presence of TPOAb, is associated with worsened obstetric outcomes.

Multiple studies have assessed associations between maternal subclinical hypothyroidism and child developmental outcomes. A metaanalysis that included 11 studies concluded that maternal subclinical hypothyroidism is significantly associated with the risk of intellectual impairment in children (OR 2.14, 95% CI: 1.20–3.83).[52] However, an individual-level metaanalysis that included 9036 mother–child pairs from three prospective population-based birth cohorts demonstrated that, while maternal FT4 levels were associated with child IQ when assessed between 1.5 and 8 years of age, no independent associations were observed between maternal TSH and child IQ.[29] Overall, while low maternal thyroid hormone availability clearly seems to be associated with adverse effects on child neurodevelopment, maternal FT4 levels appear to be a much stronger predictor than maternal TSH.

Only a few interventional trials to date have examined the effects of levothyroxine therapy on obstetric and child developmental outcomes in subclinically hypothyroid women. A trial conducted in Iran randomized 366 women who were TPOAb-negative and had serum TSH values in the range of 2.5 to 10.0 mIU/L with normal FT4 to levothyroxine dosed at 1 μg/kg/d versus no therapy starting at 12 weeks' gestation.[53] The primary outcome, preterm delivery, did not differ between the treated and untreated women in the overall analysis, but there was a significant reduction in preterm delivery (RR 0.39, 95% CI: 0.15–0.98) when analyses were restricted to only the women with baseline TSH values in the 4- to 10-mIU/L range. Two trials have examined the effects of levothyroxine treatment for subclinically hypothyroid pregnant women on child developmental outcomes. The Controlled Antenatal Screening Study (CATS) was conducted in in Italy and the United Kingdom.[54] At 3 years of age, mean IQ did not differ between the children of 390 subclinically hypothyroid or hypothyroxinemic pregnant women treated with 150 μg/day levothyroxine compared with the children of 404 untreated mothers. This trial has been criticized for initiation of therapy at 13 weeks' gestation, which may have missed a critical window for neurodevelopment in the first trimester. In addition, in light of data suggesting possible adverse effects on child IQ of both too little and too much maternal FT4,[58] the levothyroxine dose employed may have been too high. A subsequent multicenter US trial randomized 677 subclinically hypothyroid women to either levothyroxine treatment (starting at 100 μg/day) or placebo initiated at a median of 17 weeks and saw a nonsignificant 3-point increase in child IQ at age 5 years with treatment, and no difference in any obstetric outcomes, including miscarriage, preterm birth, placental abruption, and neonatal death.[55] As for the CATS study, concerns have been raised that treatment initiation in the US trial may have been too late in gestation to see effects on child development.

Given the uncertainty regarding whether levothyroxine therapy for subclinically hypothyroid pregnant women improves obstetric or child developmental outcomes, current treatment recommendations are variable. Guidelines from the American College of Obstetricians and Gynecologists recommend against treatment.[56] By contrast, the European Thyroid Association recommends treatment whenever subclinical hypothyroidism is diagnosed before conception or during gestation.[57] Because of the observed increased obstetric risks in women with both subclinical hypothyroidism and TPOAb positivity, the American Thyroid Association (ATA) recommends a stepwise approach, taking into account both the degree of TSH elevation and the patient's TPOAb status. Levothyroxine is recommended in TPOAb-positive women with subclinical hypothyroidism and in TPOAb-negative women when the serum TSH is greater than 10 mIU/L.[23] For TPOAb-negative women with TSH in the 4- to 10-mIU/L range or for TPOAb-positive women with a high-normal TSH of 2.5 to 4.0 mIU/L, levothyroxine is not routinely recommended, but may be considered. If treatment is not elected in these women, serum TSH should be monitored. Levothyroxine treatment in women with subclinical hypothyroidism should be initiated at a low dose (typically 50 μg daily) to prevent overtreatment. The goal of therapy is to maintain a serum TSH level of less than 2.5 mIU/L.

KEY POINTS

- Although subclinical hypothyroidism in pregnancy has been associated with adverse pregnancy outcomes, randomized clinical trials have not shown a clear benefit of levothyroxine treatment. Guideline recommendations are variable, but close monitoring of thyroid function should be employed if levothyroxine is not elected for subclinically hypothyroid pregnant women.

Isolated Hypothyroxinemia

Hypothyroxinemia, defined as normal serum TSH with a decreased serum FT4, reflects a multifactorial and pregnancy-specific pathophysiology likely involving iodine and iron status, angiogenic factors, and behavioral and anthropometric characteristics. Isolated hypothyroxinemia has been associated with preterm birth,[2] adverse neurobehavioral outcomes in offspring such as language delay, autistic symptoms, schizophrenia, attention deficit hyperactivity disorder, a slower reaction time, suboptimal school performance, and lower gray matter and cortex volume.[58] It remains unknown whether levothyroxine treatment for isolated hypothyroxinemia has beneficial effects. On one hand, there are observational studies that show a higher risk of various adverse outcomes. On the other hand, two randomized trials investigating the effects of treatment on offspring IQ did not show any beneficial effects. However, these randomized trials are not considered conclusive because of suboptimal study design (late treatment start, overtreatment, and a lack of statistical power). As noted earlier, the CATS trial and a subsequent US trial demonstrated no difference in mean IQ between the children of mothers treated for subclinical hypothyroidism or hypothyroxinemia and the children of untreated mothers, although the study methodology has been criticized.[54,55] One argument for the lack of effect in CATS was the relatively high levothyroxine dosage of 150 μg, which may have contributed to the lack of a net beneficial effect, as recent evidence shows that high, as well as low, FT4 concentrations are associated with suboptimal offspring neurodevelopment.[59,60] Adequately powered RCTs are still required to examine the potential effects of levothyroxine treatment in women with isolated hypothyroxinemia on offspring neurodevelopment. In light of current knowledge, it is not possible to advise for or against levothyroxine treatment for women with hypothyroxinemia. Individual risk factors such as a history of pregnancy complications or other comorbidities, as well as the potential risk for overtreatment, should be taken into account during individualized clinical decision-making.

THYROID AUTOIMMUNITY IN PREGNANCY

TPOAbs are present in 5% to 14% of pregnant women, and TgAb in 3% to 18%.[61] Risk factors for thyroid autoimmunity include older age, having a family history of autoimmune disorders, inadequate or excessive dietary iodine intake, BMI 35 kg/m^2 or higher, and European ancestry.[61,62] TPOAb and TgAb titers tend to wane over the course of gestation, likely because of the immune tolerance that develops during pregnancy. The definition of thyroid antibody positivity is typically based on assay manufacturers' recommended threshold values, but this may be problematic. An individual participant-level metaanalysis of three Dutch pregnancy cohorts demonstrated that manufacturer cutoffs for TPOAb positivity failed to identify 29% of women with TPOAb concentrations high enough to affect maternal thyroid function and pregnancy outcomes, suggesting that pregnancy-specific, population-derived cutoff values may be needed.[63] Thyroid antibodies can cross the placenta, but TPOAb and TgAb do not appear to affect fetal thyroid function.

Associated Obstetric and Fetal Outcomes

Maternal TPOAb positivity has been linked to miscarriage risk in multiple studies over the past three decades. A 2011 metaanalysis of 19 cohort studies and 12 case-control studies found a 2- to 3-fold increase in the odds of miscarriage in women with thyroid autoantibodies (OR 3.90, 95% CI: 2.48–6.12 for the cohorts and OR 1.80, 95% CI: 1.25–2.60 for the case-control studies).[64] This finding has been confirmed in a subsequent prospective Chinese cohort, with a similar increased risk for miscarriage seen in euthyroid, thyroid antibody–positive women compared with euthyroid women without antibodies (OR 2.71, 95% CI: 1.43–5.12).[51] The association between maternal autoimmunity and recurrent miscarriage, defined as three or more pregnancy losses, has been somewhat variable across studies, but a recent metaanalysis of 22 studies concluded that TPOAb positivity was associated with increased risk (random effects OR 1.76; 95% CI: 1.00–3.10).[65]

Preterm delivery has also been associated with TPOAb positivity in numerous studies. A 2011 metaanalysis that included five cohorts, together comprising 12,566 women, concluded that the risk for preterm delivery was increased 2-fold in women with thyroid autoimmunity (OR 2.07, 95% CI: 1.17–3.68).[64] A larger 2012 metaanalysis of 11 prospective cohort studies comprising 35,467 women also reported an increase in the risk for premature delivery in euthyroid women with TPOAb compared with antibody-negative women (RR 1.69, 95% CI: 1.19–2.41) but no increase in risk of prematurity for TgAb-positive women (RR 0.88, 95% CI: 0.60–1.29).[66] Most recently, an individual participant-level metaanalysis including 47,045 participants from 19 cohorts found that, compared with TPOAb-negative women, TPOAb-positive women were at increased risk for both preterm birth (OR 1.33, 95% CI: 1.15–1.56) and very preterm birth (OR 2.45, 95% CI: 1.81–3.32).[2] In this analysis, TgAb positivity was not associated with increased preterm delivery risk (OR 0.88, 95% CI: 0.64–1.20).

Few studies have assessed associations of maternal TPOAb and risk for obstetric outcomes other than miscarriage and prematurity. Based on current evidence, there is likely no association of maternal TPOAb status with preeclampsia or gestational hypertension.[62] Two studies to date suggest a possible link between maternal TPOAb positivity and risk for placental abruption, two studies have documented an association with premature rupture of membranes, and one study has found an association between TPOAb status and risk for polyhydramnios, while studies examining associations with gestational diabetes have been inconclusive.[62] Equivocal evidence suggests a possible link between maternal TPOAb status and child neurodevelopmental outcomes, independent of maternal thyroid function. An analysis of 1268 Chinese mother–child pairs found that maternal TPOAb positivity in gestation was associated with below-average child mean intelligence (OR 6.69, 95%: CI 2.34–19.15) and motor scores (OR 8.25, 95% CI: 3.31–20.53) at 25 to 30 months of age.[67] An analysis of associations between maternal TPOAb positivity during gestation and child IQ, assessed at 5 to 10 years of age, in two European pregnancy cohorts found that TPOAb positivity was associated with a 2.0 ± 0.9-point decrement in mean child IQ in one of the cohorts ($P = .03$), but found no association of maternal TPOAb status with child IQ in the other.[68] These results were not altered by adjustment for maternal thyroid function. Additional research will be needed to better understand the effects of TPOAb positivity on obstetric outcomes other than pregnancy loss and on child neurodevelopmental outcomes.

Potential Mechanisms for Associations

The mechanism for the observed associations between thyroid autoimmunity and pregnancy loss is unknown, although several theories have been advanced. It has been argued that the associations reported between thyroid autoimmunity and pregnancy loss in some cohort studies may simply be attributed to confounding by factors such as older maternal age or higher TSH values within the reference range in the antibody-positive women, although independent associations have been seen in some studies that have controlled for these variables. Women with TPOAb positivity do not experience the normal physiologic hCG-mediated rise in FT4 and decline in serum TSH levels that are observed early in pregnancy in women without thyroid autoimmunity.[69] They tend to have higher serum TSH levels throughout gestation than women who are TPOAb-negative and are at increased risk for the development of hypothyroidism as pregnancy progresses.[63,70] It is, therefore, possible that the association between TPOAb positivity and increased risk for pregnancy loss is mediated by mildly decreased thyroid hormone levels. However, it is also plausible that this association has nothing to do with maternal thyroid status, and that TPOAbs are instead simply markers for an autoimmune milieu. Maternal thyroid autoimmunity is known to be associated with impaired cellular and humoral immune responses and with an increased prevalence of anticardiolipin and other non-organ-specific autoantibodies.[61] Finally, TSH receptor–blocking antibodies are found in up to 10% of patients with Hashimoto thyroiditis. Because of cross-reactivity between TSH receptor–blocking antibodies and the receptors for hCG, these blocking antibodies may inhibit the LH/hCG-receptor in the corpus luteum, causing early pregnancy loss via decreased progesterone and estrogen production.[71]

Implications for Therapy and Monitoring

In the absence of a clear understanding of the mechanism for the observed association between maternal TPOAb positivity and pregnancy loss, it is difficult to be certain of the appropriate intervention, if any. Small studies have investigated treatments designed to reduce autoimmunity. Results of three nonrandomized studies investigating the use of intravenous immunoglobulin therapy to reduce rates have been inconclusive, and such treatment is currently not recommended.[23] Two small randomized clinical trials suggested an improvement in clinical pregnancy and live birth rates in TPOAb-positive women who received prednisolone before undergoing ART, but current guidelines recommend against glucocorticoid therapy for autoantibody-positive euthyroid women undergoing ART in light of uncertainty regarding both risks and benefit.[23]

Several trials have now explored whether levothyroxine therapy for euthyroid, TPOAb-positive pregnant women improves pregnancy outcomes. In a 2006 study, Negro and colleagues randomized 57 TPOAb-positive euthyroid women to treatment with levothyroxine starting at 10 weeks' gestation.[72] Compared with 58 women randomized to no treatment, there was a significant decrease in risk for both miscarriage (RR 1.72, 95%: CI 1.13–2.25) and preterm delivery (RR 1.66, 95% CI: 1.18–2.34). Subsequent trials have failed to replicate those results. Nazarpour and colleagues randomized 131 TPOAb-positive pregnant women with serum TSH values 10 mIU/L or less to levothyroxine (using the same dosing protocol as Negro et al.) versus no therapy and found a lower risk for preterm delivery in the treated versus the untreated group (RR 0.30, 95%: CI 0.1–0.85).[73] However, in sensitivity analyses, the benefit in this trial accrued only to those women with a baseline serum TSH greater than 4.0 mIU/L. Two larger trials have investigated the effects of levothyroxine in TPOAb-positive women when initiated preconception. The POSTAL study randomized TPOAb-positive, euthyroid women with infertility to 25 to 50 μg levothyroxine daily versus no treatment starting before IVF and continued through delivery.[3] Treatment was not associated with any effect on rates of miscarriage (rate difference [RD] –0.34%, 95% CI: –8.65 to 8.12) or live birth (RD –0.67%, 95% CI: –8.09 to 6.77). Most recently, the TABLET trial enrolled 952 euthyroid TPOAb-positive women with a history of infertility or miscarriage who were trying to conceive either naturally or through ART.[19] Women were randomized to 50 μg levothyroxine daily versus placebo, started preconception and continued until delivery. Levothyroxine therapy was not associated with any difference in live birth rates (RR 0.97, 95% CI: 0.83–1.14).

No therapy can currently be definitively recommended for women who are TPOAb-positive and euthyroid either in pregnancy or preconception. It is, however, important to remember that those women are at risk for the development of hypothyroidism during gestation. Guidelines currently recommend measurement of serum TSH when pregnancy is diagnosed and every 4 weeks through midpregnancy in women who are known to be TPOAb-positive.[23]

KEY POINTS

- Maternal TPOAb positivity has been linked to increased risks for miscarriage and preterm delivery, but mechanisms for these associations are uncertain. No therapy to date has demonstrated a benefit for TPOAb positive euthyroid women. TPOAb positive women are at increased risk for the development of hypothyroidism during gestation, and their serum TSH levels should be monitored.

SCREENING FOR THYROID DYSFUNCTION IN PREGNANCY

Whether or not all pregnant women should be routinely screened for thyroid dysfunction has been highly controversial.[74] Screening would largely be targeted toward the detection of hypothyroidism, as women with overt hyperthyroidism are likely to present with symptoms, and women who are subclinically hyperthyroid in pregnancy do not require treatment. It is estimated that universal screening may detect overt hypothyroidism in approximately 0.5% of pregnant women,[30] for whom intervention is likely to improve both obstetric and child developmental outcomes. One study has reported that thyroid screening is cost effective on the basis of the detection of overt hypothyroidism alone.[75] However, universal screening would also detect approximately 3.5% of women with subclinical hypothyroidism and 2.5% of women with isolated hypothyroxinemia (if testing includes FT4), for whom a benefit of therapy is uncertain. Universal screening would increase medical costs, could increase patient anxiety, and may lead to misinterpretation of thyroid function testing. Clinical practice guidelines regarding thyroid function testing in pregnancy are inconsistent, with some organizations advocating for universal screening, some for broadly targeted case-finding, and some for only very limited thyroid testing. The ATA does not recommend either for or against universal screening, but does endorse TSH testing for pregnant women considered to be at high risk for hypothyroidism, including those with suggestive symptoms, a personal or family history of thyroid disease or autoimmunity, a history of miscarriage or infertility, morbid obesity, age over 30 years, or two or more prior pregnancies.[23] A recent retrospective analysis in a single center concluded that these current case-finding criteria would detect fewer cases of subclinical hypothyroidism than a universal screening strategy, but that the proportion of women with overt hypothyroidism identified by each strategy did not differ.[76]

THYROID NODULES AND CANCER DURING PREGNANCY

The prevalence of thyroid nodules in pregnancy varies based on population iodine intakes. Thyroid nodules have been reported in up to one-third of pregnant women.[34] Stimulation of the thyroidal TSH receptor by hCG in early pregnancy and depletion of intrathyroidal iodine stores over the course of gestation in mildly to moderately iodine-deficient regions may be drivers of nodule growth in pregnant women. Among 221 Chinese pregnant women followed prospectively with ultrasonography during pregnancy, 15% had nodules at least 2 mm in size during the first trimester, with nodules being more frequent in older women and those with higher gravidity.[77] Nodule volumes increased over the course of gestation, and sizes remained increased at 3 months postpartum. Eleven percent of participants developed new nodules during pregnancy. Thyroid cancer is also relatively common in women of childbearing age. A retrospective analysis including 4,846,505 deliveries that occurred in California from 1991 to 1999 found that 3.3/10,000 women had thyroid cancer diagnosed within 9 months before pregnancy, 0.3/100,000 had cancer diagnosed at the time of delivery, and 10.8/100,000 were diagnosed within 1 year postpartum.[78]

Decisions about the need for thyroid fine-needle aspiration (FNA) biopsy in pregnant women should be based on the same ultrasonographic patterns that are used outside the pregnancy setting. FNA biopsy is safe during gestation and should generally be performed for suspicious nodules when serum TSH is not suppressed. Radioactive iodine scanning is contraindicated in pregnant women, so when low serum TSH values persist beyond week 16 of pregnancy it is reasonable to defer FNA biopsy until after delivery, when radionuclide scanning can be used to determine whether nodules are hyperfunctioning. When benign FNA biopsy results are obtained before or during gestation, pregnancy should not alter the usual nodule surveillance strategy. For nodules with indeterminate FNA cytopathology, in most cases surgery or repeat biopsy can be safely deferred until after delivery. Testing with molecular markers is not recommended, because these tests have not been evaluated in pregnancy, and it is biologically plausible that gene expression, and thus test validity, may be altered during gestation.[23] Some women prefer to defer FNA biopsy or to defer surgery for suspicious nodules until after delivery. This appears safe based on retrospective data. A cohort that included 61 women whose thyroid cancer was diagnosed during pregnancy found that long-term (median 22.5 years) outcomes did not differ among the 14 women who opted for thyroid surgery during pregnancy, the 47 who deferred surgery until after delivery, and 528 age-matched controls who had not been pregnant at the time of their cancer diagnosis.[79] Another retrospective series followed 19 patients who were diagnosed with papillary thyroid cancer just before or during the early stages of pregnancy and elected to defer surgery until after delivery.[80] The median tumor size at diagnosis was 0.9 cm, and the median duration from diagnosis to surgery was 11.9 months. Serial ultrasonography during pregnancy demonstrated no clinically meaningful change in tumor size and no development of lymph node metastases. Finally, among 50 Japanese women undergoing active surveillance for low-risk papillary carcinomas who experienced 51 pregnancies from 1993 to 2013, pregnancy was associated with an increase in tumor size in only 8%, and none of the patients developed nodal metastases.[81]

In most cases, when papillary thyroid cancer is detected in early pregnancy surgery may be deferred until after delivery.[23] Serial ultrasound should be performed, and surgery during pregnancy may be considered if there is substantial growth before 24 to 26 weeks' gestation or if cytologically malignant cervical lymph nodes are present. When surgery is deferred, levothyroxine may be initiated to maintain the serum TSH between 0.3 and 2.0 mIU/L for the remainder of gestation. It is unclear whether pregnancy alters tumor aggressiveness. Stimulation of TSH receptor by hCG may promote tumor growth, and some differentiated thyroid cancers express estrogen receptor, which may also predispose them to growth during gestation.[82] A retrospective study of 123 Italian women with differentiated thyroid cancer found that diagnosis during pregnancy or in the first year postpartum was associated with higher risk for persistent or recurrent disease (60%) than diagnosis more than a year postpartum (4%) or diagnosis in women who had never been pregnant (13%). Disease persistence/recurrence was primarily defined by elevated serum thyroglobulin levels, and it is possible that pregnancy may have influenced the completeness of the initial thyroid surgery, and therefore confounded the study results. Another retrospective Italian study included 340 women with differentiated thyroid cancer and similarly reported higher risk for persistent or recurrent disease when women were diagnosed during or within 2 years following pregnancy (10.5%) compared with women who were diagnosed at least 2 years after delivery (1.3%) or nulliparous women (4.7%).[83] Tumor persistence/recurrence was not clearly defined, but likely was based on serum thyroglobulin. In both Italian studies, delaying surgery until after delivery did not appear to influence risk. Although only limited data are available regarding the course of anaplastic and medullary thyroid cancer in pregnancy, surgery should not be delayed when these cancers are diagnosed in pregnant women. For women who require thyroid surgery in pregnancy, the second trimester is safest, although the risk of complications of thyroid surgery may still be increased.[84]

A prior history of treated cancer should not be a deterrent to pregnancy plans. Tumor surveillance strategies during gestation should be guided by the ATA disease response category.[85] A single-center retrospective analysis examined 235 women with differentiated thyroid cancer who had a term pregnancy following initial cancer treatment between 1997 and 2015.[86] When evaluated 3 to 12 months after delivery, none of the 197 women who had an ATA excellent, indeterminate, or biochemical incomplete response to therapy before pregnancy had developed structural disease. However, among the 38 women with a structural incomplete response to therapy prepregnancy, worsened structural disease (a ≥3-mm increase in the size of known disease or new metastases) was identified after delivery in 11 (29%), of whom three (8%) required additional treatment. Therefore, additional tumor surveillance is not required during pregnancy for women with an excellent or indeterminate response to therapy, but additional ultrasound and thyroglobulin monitoring are reasonable in women with a known incomplete response to therapy.

Numerous studies have investigated whether a history of radioactive iodine treatment is associated with impaired fertility or adverse pregnancy outcomes. A recent systematic review found that that menstrual irregularities occur in the first year after treatment in up to 31% of patients, that anti-Mullerian hormone levels are significantly lower 1 year after treatment compared with baseline (mean difference 1.50 ng/mL, 95% CI: 0.82–2.17), and that menopause may occur at a slightly younger age in treated compared with untreated women (49.5 years vs. 51 years; $P < .001$).[87] However, in the same paper, a metaanalysis of four studies showed that women with prior radioactive iodine treatment were not at lower risk of becoming pregnant compared with controls (OR 0.98, 95% CI: 0.72–1.33).[87] A review of 54 studies found no evidence for an increase in miscarriage, congenital malformations, or premature delivery in women who had received radioactive iodine treatment before pregnancy, although it noted that transient menstrual irregularities can be expected in approximately 30% of women following radioactive iodine therapy.[88] More recently, a Korean population-based cohort study included 111,459 women of childbearing age who underwent thyroidectomy with or without radioactive iodine treatment for thyroid cancer.[89] Among the 10,842 women who became pregnant, miscarriage, preterm delivery, and congenital malformation rates did not differ between those who received radioactive iodine treatment compared with those who did not (32.1% vs. 30.7% for miscarriage, 12.9% vs. 12.8% for preterm delivery, and 9.0% vs. 8.9% for congenital malformations). However, in a subgroup analysis examining the time interval between radioactive iodine therapy and conception, 18 cases of congenital malformation were observed among women who became pregnant less than 6 months after radioactive iodine treatment, and the odds ratio for congenital malformation (adjusted for maternal age and cumulative radioactive iodine dose) was 1.74 (95% CI: 1.01–2.97; $P = .04$) for women who conceived up to 5 months after treatment compared with those who conceived 12 to 23 months after treatment. Overall, it appears that, although there may be transient menstrual irregularities following radioactive iodine treatment, radioactive iodine therapy does not substantially impair either fertility or subsequent pregnancy outcomes as long as pregnancy is postponed at least 6 months after ablation therapy.

KEY POINTS

- In most instances, surgery for thyroid cancer diagnosed during pregnancy can be safely deferred until after delivery. A prior history of thyroid cancer should not be a deterrent to pregnancy, but tumor surveillance should be intensified during pregnancy for women with known persistent or residual tumor.

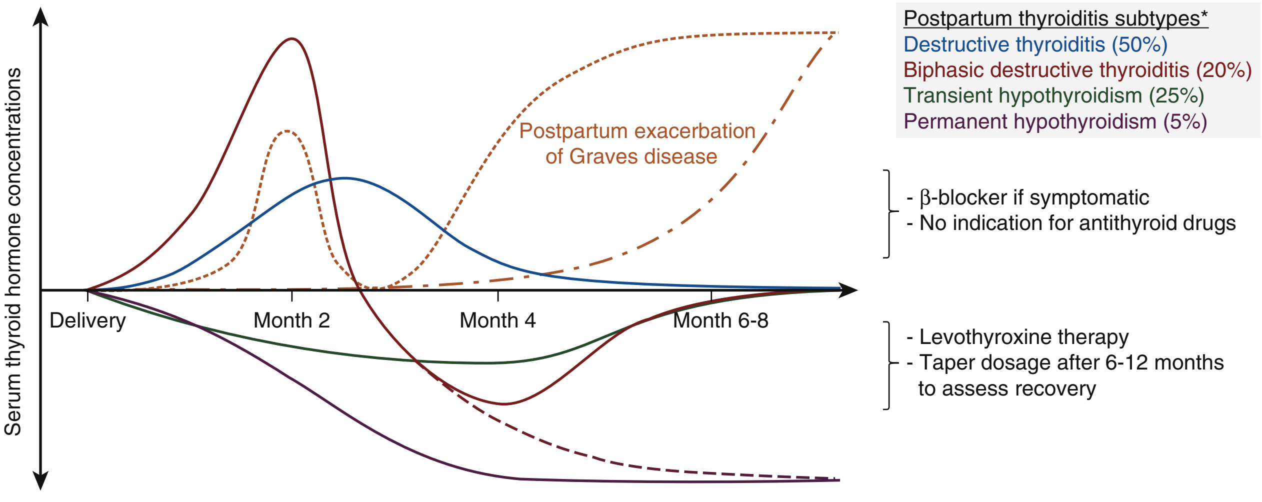
THYROID DISORDERS IN THE POSTPARTUM PERIOD

Postpartum Thyroiditis

Postpartum thyroiditis (PPT) is destructive thyroiditis occurring during the first 12 months postpartum. It likely results from a rebound of autoimmunity following the normal state of immune tolerance induced by pregnancy. It occurs in approximately 5% to 8% of women and is more frequent in women with TPOAb positivity in early pregnancy and in those with a personal or family history of autoimmune disorders.[90,91] PPT may occur following miscarriage. It can also occur in women receiving levothyroxine for mild preexisting hypothyroidism.[92] The typical sequence is a 4- to 8-week period of thyrotoxicosis caused by leakage of preformed hormone from the thyroid gland into the bloodstream, followed by a 4- to 6-month period of transient hypothyroidism (Fig. 75.6). However, only the thyrotoxic phase is seen in 50% of women, and only hypothyroidism in 25%. While most women will become euthyroid again within a year, up to 20% will be left with chronic hypothyroidism, and up to half will develop chronic hypothyroidism after an initial recovery.[90] PPT recurs after 70% of subsequent pregnancies.

New or recurrent Graves hyperthyroidism may present after delivery and must be distinguished from PPT in the postpartum setting. Antibody testing may help to establish the etiology of thyrotoxicosis, as TPOAbs are positive in most women with PPT, but the presence of TRAbs is highly sensitive and specific for Graves disease.[93] The ratio of serum T3 to T4 is generally less than 20:1 in PPT but is often higher in women with Graves hyperthyroidism.[94] Most women with PPT have only mild thyrotoxic symptoms, so the presence of severe thyrotoxic symptoms favors a diagnosis of Graves disease. Timing of onset may also provide some clues, with thyrotoxicosis from PPT presenting most frequently from 1 to 4 months postpartum, whereas Graves disease usually presents at 6 to 12 months postpartum or later.[91] Although rarely employed since the advent of sensitive and specific TRAb assays, the 24-hour radioactive iodine uptake test can be used to differentiate between Graves disease, in which uptake is elevated, and PPT, in which the uptake is low or undetectable.

Palpitations and other symptoms of the thyrotoxic phase of PPT can be managed with a β-adrenergic antagonist such as metoprolol or propranolol that is safe in lactation. ATDs do not have a role in destructive thyroiditis and should not be used. Levothyroxine should



*Up to 20% of women who initially return to a euthyroid state will develope chronic hypothyroidism later in life.

Fig. 75.6 Trajectories of postpartum thyroiditis subtypes.

be initiated in the hypothyroid phase of PPT if women are symptomatic or are actively trying to conceive. Because hypothyroidism is usually transient, levothyroxine doses can be tapered after 6 to 12 months of therapy to determine whether underlying thyroid function has recovered. Women with a history of PPT should have annual TSH monitoring, because they remain at high risk for the development of chronic hypothyroidism. Trials of iodine supplementation and levothyroxine for TPOAb-positive pregnant women have not shown any benefit for the prevention of PPT.[61] Trials of selenium supplementation for the prevention of PPT in TPOAb-positive women have had mixed results, and, in light of potential side effects, such supplementation is not currently recommended.[23,95]

KEY POINTS

- Graves disease must be differentiated from postpartum thyroiditis when thyrotoxicosis presents in the postpartum setting. Symptoms in the thyrotoxic phase of postpartum thyroiditis can be managed with a β-adrenergic antagonist, and levothyroxine may be required in the hypothyroid phase if symptoms are present or conception is desired.

Considerations in Lactating Women

Case reports and animal studies suggest that maternal hypothyroidism will suppress milk production in lactating women; the effects of maternal hyperthyroidism on milk production are largely unknown. TSH testing is advocated in women who have difficulty with lactation in the absence of other known causes, and levothyroxine should be initiated if hypothyroidism is identified.[23,91] Only trace amounts of maternal thyroid hormone are present in breast milk, so maternal thyroid dysfunction or levothyroxine ingestion does not alter the thyroid status of breastfed infants (for effects of maternal ATD ingestion, see earlier).

Sodium-iodide symporter (NIS) is expressed in the lactating breast and actively concentrates iodine in breast milk, where it serves as a critical nutritional source for the breastfed infant.[96] Therefore, women who are lactating have increased iodine requirements, and iodine supplementation is recommended for lactating women in regions where iodine intake is inadequate.[23] Because radioactive iodine is concentrated in breast milk, the use of ^{131}I is absolutely contraindicated in women who are lactating owing to concerns about transmission to the breastfed infant and radiation-induced damage to breast tissue.[23] It is recommended that women who require radioactive iodine therapy for hyperthyroidism or thyroid cancer should cease lactation at least 6 weeks, and optimally at least 3 months, before treatment to allow regression of lactation-induced NIS expression.[97] ^{123}I may safely be used for scanning and uptake testing in lactating women if breast milk is pumped and discarded for 3 to 4 days. Similarly, use of Tc-99m pertechnetate requires breast milk to be pumped and discarded for 24 hours after scanning.[23]

SUMMARY AND FUTURE DIRECTIONS

Approaches to the diagnosis and treatment of thyroid disorders may differ in women during preconception, pregnancy, and the postpartum period. Thyroid function tests must be interpreted using gestation-specific reference ranges. In most regions, additional studies are needed to derive gestation-specific, assay-specific laboratory reference ranges for TSH and FT4 and to determine optimal assay-specific thresholds for TPOAb positivity. Thyroid dysfunction is associated with an increased risk for infertility; however, prospective studies are needed to better understand the impact of preconception thyroid function on both fertility and pregnancy outcomes. Overt hypothyroidism in pregnancy requires levothyroxine treatment to prevent adverse obstetric and child neurodevelopmental outcomes. Whether to treat subclinical hypothyroidism in pregnancy remains controversial. Adequately powered trials to assess whether initiation of levothyroxine in early gestation are needed but may be challenging to conduct. Recent large registry studies have demonstrated teratogenicity of both MMI and PTU when used in the first trimester of pregnancy. This has led to an increased emphasis on preconception counseling of women with Graves disease, with consideration of definitive therapy. When ATDs are used in pregnancy, close monitoring and dose titration are essential. Prospective data are needed to inform optimal strategies for ATD use in pregnancy, particularly whether to change from PTU to MMI after organogenesis is complete. TPOAb positivity is associated with an increased risk for miscarriage and preterm delivery even in euthyroid women, but particularly when cooccurring with subclinical hypothyroidism. Future studies will be needed to better understand associations of maternal TPOAb with obstetric outcomes other than pregnancy loss and with child neurodevelopmental outcomes. Current data do not support levothyroxine treatment for euthyroid, TPOAb-positive women. Studies to better understand the mechanisms behind the observed associations between TPOAb positivity and pregnancy loss will be needed to inform new interventional strategies. The workup of thyroid nodules in pregnancy must take into account patient preferences regarding the timing of biopsy and surgery, as well as ultrasonographic patterns. In women who are thyroid cancer survivors, tumor surveillance strategies during gestation can be guided by the ATA disease response category and should be more aggressive in those with a known structural incomplete response to therapy. Finally, PPT is common, particularly among TPOAb-positive women. It is important to monitor TSH periodically in women with a history of PPT because they are at high risk for the development of chronic hypothyroidism.

Bernard Courtois, a French chemist, discovered iodine (atomic weight 126.9) in 1811. He gave the purple crystals to Gay-Lussac, who identified it as a new element and named it “iode,” from the Greek *ιώδης* (i.e., *violet*).[1] In 1819, Jean-François Coindet, in Geneva, reported treating goiter with tincture of iodine. The connection between goiter, myxedema, and iodine was established in 1896, when Baumann and Roos discovered iodine in the thyroid.[1] In the early twentieth century, groundbreaking studies by Swiss and American scientists showed the efficacy of iodine prophylaxis in the prevention of goiter and cretinism. The first use of salt iodization as a public health measure was in northern Switzerland in the early 1920s.[1]

DIETARY SOURCES OF IODINE

Absorption and Bioavailability of Iodine

Iodine (as iodide) is widely but unequally distributed in the Earth’s environment.[2] In many regions, leaching from flooding and erosion have exhausted soils of iodide, and crops grown in these soils will be low in iodine, and humans and animals consuming food grown in these soils become iodine-deficient. Iodine deficiency in these areas will persevere until iodine enters the food chain through dietary diversification using foods produced outside the iodine-deficient area or fortification of iodine in foods (e.g., iodization of salt). The native iodine content of most foods and beverages is small; commonly-consumed foods provide only 3 to 80 μg per serving.[3] Key dietary sources of iodine in industrialized countries like the United States and Switzerland are milk and bread (containing iodized salt).[3,4] In many countries, iodized salt used in the household is the major dietary source. Dietary supplements frequently contain potassium iodide at amounts in the range of 50 to 250 μg.[5]

Iodide is rapidly and nearly entirely absorbed (>90%) in the stomach and duodenum.[5] Iodide absorption in the gut is thought to be largely passive, but active absorption may also occur through the sodium/iodide symporter (NIS)[6] and the sodium/multivitamin transporter[7]; both are present in the gut mucosa. Organically bound iodine is usually digested and the freed iodide absorbed, but some forms may be absorbed intact; for example, approximately 70% of an oral dose of thyroxine (T_4), is absorbed intact.[8]

Thyroidal Iodine Uptake

Iodine is cleared from the bloodstream mostly by the thyroid and kidney, and while renal iodine clearance is fairly constant, thyroid clearance varies strikingly depending on the chronic intake of iodine. In conditions of sufficient dietary iodine supply, the thyroid normally takes up less than 20% of absorbed iodine. In chronic iodine deficiency, this portion can exceed 80%.[9] Iodine in the blood is turned over quickly; normally, plasma iodide has a half-life of approximately 10 hours, but this is reduced in iodine deficiency or hyperthyroidism.[9] The body of a healthy adult contains up to 20 mg of iodine, of which 70% to 80% is in the thyroid.[9] In chronic iodine deficiency, the amount of iodine in the thyroid may fall to less than 20 μg. In iodine-sufficient areas, the adult thyroid traps approximately 60 μg of iodine per day to balance losses and support thyroid hormone synthesis. The NIS, a protein in the basolateral thyrocyte membrane, moves iodide into the thyroid at a concentration gradient 20 to 50 times that of plasma.[10] It concentrates iodine by active transport that uses energy released by the inward translocation of sodium down its electrochemical gradient to drive the simultaneous inward translocation of iodine against its electrochemical gradient.[10] Metabolism of circulating thyroid hormone in peripheral tissues liberates iodine that joins the plasma iodine pool and can be cleared by the thyroid or kidney. Greater than 90% of ingested iodine is eventually excreted in the urine, with only a minor amount appearing in the feces and sweat.[9]

Goitrogens

Although iodine deficiency is typically the underlying cause of endemic goiter, a range of naturally occurring compounds and environmental

TABLE 76.1 Recommendations for Iodine Intake (µg/day) by Age or Population Group

Population group	US Institute of Medicine[7]		Population Group	World Health Organization[22]
	EAR	AI* or RDA		RNI
Infants 0–12 mo	—	110–130*	Children 0–5 y	90
Children 1–8 y	65	90	Children 6–12 y	120
Children 9–13 y	73	120		
Adults ≥14 y	95	150	Adults >12 y	150
Pregnancy	160	220	Pregnancy	250

EAR, Estimated average requirement; *AI*, adequate intake; *RDA*, recommended daily allowance; *RNI*, recommended nutrient intake.

pollutants may disrupt thyroid function and be goitrogenic.[11] Cruciferous vegetables, including cabbage, kale, cauliflower, broccoli, turnips, and rapeseed, contain glucosinolates; their metabolites compete with iodine for thyroidal uptake. Cassava, lima beans, linseed, sorghum, and sweet potato contain cyanogenic glucosides; these may be metabolized to thiocyanates that also compete with iodine for thyroidal uptake. An example is linamarin, a thioglycoside found in cassava, a staple food in many developing countries. If cassava is not sufficiently soaked or cooked to eliminate the linamarin, it is hydrolyzed in the gut to release cyanide, which is metabolized to thiocyanate. Soy and millet contain flavonoids that may impair activity of the thyroid peroxidase enzyme. Nearly all goitrogens are clinically relevant only if dietary iodine supply is low and/or goitrogen intake is high and prolonged. Dietary deficiencies of selenium, iron, and vitamin A aggravate the effects of iodine deficiency. Glutathione peroxidase and the deiodinases are selenium-dependent enzymes. In selenium deficiency, accumulated peroxides may damage the thyroid, and deiodinase deficiency reduces thyroid hormone synthesis.[12] Iron deficiency limits heme-dependent thyroid peroxidase activity and impairs thyroid hormone synthesis. In areas of endemic goiter, iron deficiency anemia diminishes the efficacy of iodine prophylaxis, while iron supplementation improves the effectiveness of iodized oil and iodized salt.[13] Vitamin A deficiency in iodine-deficient children triggers thyroid-stimulating hormone (TSH) hyperstimulation of the thyroid and increased risk for goiter through decreased vitamin A-mediated suppression of the pituitary *TSHβ* gene.[14]

KEY POINTS

- Most foods have low amounts of iodine, and diets in many countries cannot provide adequate iodine without iodine fortification of salt.

METABOLISM

Thyroidal Adaptation to Iodine Deficiency

The thyroid adjusts to low intakes of dietary iodine by distinct changes in its activity. In most adults, if iodine intake drops below approximately 100 µg/day, TSH secretion is augmented. This increases plasma iodide clearance by the thyroid through stimulation of NIS expression.[15] As the thyroid clears a larger fraction of circulating iodide, there is a gradual reduction in renal iodide excretion, and the urinary iodine concentration falls. However, in most healthy adults, as long as daily iodine intake is at least approximately 60 µg, despite a reduction in circulating plasma inorganic iodine and urinary iodine, absolute uptake of iodine by the thyroid and thyroidal iodine stores remain sufficient. Below approximately 60 µg, despite maximal fractional clearance of circulating iodine by the thyroid, absolute uptake falls, the iodine content of the thyroid is exhausted, and many people develop goiter.[9]

Goiter and thyroid hyperplasia produced by iodine deficiency are accompanied by altered thyroid hormone synthesis. Poorly iodinated thyroglobulin in the colloid leads to an increase in monoiodotyrosine and T_3 and a decrease in diiodotyrosine and T_4. The typical pattern of circulating thyroid hormones in children in areas of moderate-to-severe iodine deficiency is a variably elevated TSH, a normal or high-normal serum T_3, and a low serum T_4; this pattern is also seen in adults, but less predictably.[16] The serum thyroglobulin (Tg) concentration is usually elevated. The increased serum T_3/T_4 ratio is important in the adaptation to iodine deficiency because T_3 has approximately four times the metabolic potency of T_4 but requires only 75% as much iodine for its synthesis. Thyroid failure and cretinism typically develop only in regions of chronic, severe iodine deficiency, where most individuals have low circulating T_4 and T_3 and dramatically elevated TSH.[12,16]

Iodine Requirements

Recommended daily intakes for iodine are shown in Table 76.1. The World Health Organization (WHO)[17] uses the Recommended Nutrient Intake (RNI) to define iodine requirements; the RNI is the intake estimated to cover the needs of "nearly all" healthy individuals in the specified life stage. The US Institute of Medicine uses the Recommended Dietary Allowance (RDA), which is the average daily intake sufficient to meet the iodine requirement of 97% to 98% of healthy individuals in a life stage.[5]

The iodine requirement during pregnancy is increased due to: (a) an increase in maternal T_4 synthesis to preserve maternal euthyroidism and transfer thyroid hormone to the fetus early in the first trimester, before the fetal thyroid is active, (b) iodine transfer to the fetus, chiefly in later gestation, and (c) an increase in renal iodine clearance.[18] The WHO recommends a daily iodine intake of 250 µg/day for pregnant women.[17] A recent study in healthy infants suggested that the iodine requirement in 2- to 5-month-old infants is 70 µg/d; this would correspond to an RDA of 80 µg.[19] Thus, the current adequate intake of 110 to 130 µg/day for infants[5] may exceed actual requirements.

KEY POINTS

- The thyroid can adapt to moderately-low intakes of iodine by increasing plasma iodide clearance. Iodine requirements vary by age and life stage.

METHODS TO ASSESS IODINE STATUS

Urinary Iodine Concentration

Because greater than 90% of dietary iodine ultimately appears in the urine,[9] urinary iodine concentration (UIC) is an excellent indicator of recent iodine intake. UIC can be expressed as a concentration (µg/L), relative to creatinine excretion (µg iodine/g creatinine), or as 24-hour

TABLE 76.2 Epidemiologic Criteria for Assessment of Iodine Nutrition in a Population Based on Median or Range of Urinary Iodine Concentrations

	Iodine Intake	Iodine Nutrition
School-aged children		
<20 μg/L	Insufficient	Severe iodine deficiency
20–49 μg/L	Insufficient	Moderate iodine deficiency
50–99 μg/L	Insufficient	Mild iodine deficiency
100–299 μg/L	Adequate	Optimum
>300 μg/L	Excessive	Risk of adverse health consequences (iodine-induced hyperthyroidism, autoimmune thyroid disease)
Pregnant women		
<150 μg/L	Insufficient	
150–249 μg/L	Adequate	
250–499 μg/L	More than adequate	
≥500 μg/L[a]	Excessive	
Lactating women[b]		
<100 μg/L	Insufficient	
≥100 μg/L	Adequate	
Children less than 2 years of age		
<100 μg/L	Insufficient	
≥100 μg/L	Adequate	

[a] The term excessive means in excess of the amount needed to prevent and control iodine deficiency.

[b] In lactating women, the numbers for median urinary iodine are lower than the iodine requirements, because of the iodine excreted in breast milk.

(From World Health Organization, United Nations Children's Fund, International Council for the Control of Iodine Deficiency Disorders. Assessment of iodine deficiency disorders and monitoring their elimination. A guide for programme managers. 3rd ed. Geneva: World Health Organization; 2007; Zimmermann MB, Aeberli I, Andersson M, et al. Thyroglobulin is a sensitive measure of both deficient and excess iodine intakes in children and indicates no adverse effects on thyroid function in the UIC range of 100-299 μg/L: a UNICEF/ICCIDD study group report. *J Clin Endocrinol Metab.* 2013;98:1271–1280; WHO Secretariat, Andersson M, de Benoist B, et al. Prevention and control of iodine deficiency in pregnant and lactating women and in children less than 2-years-old: conclusions and recommendations of the Technical Consultation. *Public Health Nutr.* 2007;10:1606–1611.)

excretion (μg/day). For population surveys, UIC should be measured in spot urine specimens from a representative sample of the target group and expressed as the median, in μg/L[17] (Table 76.2). Although the median UIC (mUIC) does not provide specific information on thyroid function, a low value implies that a population is at greater risk of developing thyroid disorders.[20] The mUIC is a reliable indicator of iodine status in populations, but its value for gauging individual status is reduced by high day-to-day variability in iodine intakes.[9] In European adults, intraindividual variation in UIC is 35% for both 24-hour collections and spot samples, so that urine samples from approximately 10 different days are required to assess individual iodine status with 20% precision.[21]

Thyroid Size

Two methods are available for determining if a goiter is present: neck inspection and palpation, and thyroid ultrasonography. By palpation, a thyroid is considered goitrous when each lateral lobe has a volume greater than the terminal phalanx of the thumbs of the subject being examined.[17] Goiter surveys are frequently done in school-age children. However, palpation of goiter in areas of mild iodine deficiency has poor sensitivity and specificity; in such areas, measurement of thyroid volume by ultrasound is superior. Thyroid ultrasound is quickly done and feasible in remote areas using compact equipment, and references for thyroid volume are available from iodine-sufficient children.[17] In areas of endemic goiter, although thyroid size predictably declines in response to increases in iodine intake, thyroid size may not return to normal for months or years after correction of iodine deficiency. During this transition period, the goiter rate is problematic to interpret, because it reflects both a population's history of iodine nutrition and its present status. A sustained salt iodization program will reduce the goiter rate to less than 5% in school-age children, and this denotes disappearance of iodine deficiency as a significant public health problem.[22]

Thyroid-Stimulating Hormone

Circulating TSH is an indirect indicator of iodine nutrition because its concentration in blood is determined largely by circulating thyroid hormone, which in turn reflects iodine intake. However, in older children and adults, although serum TSH may be variably increased by iodine deficiency, values frequently remain within the normal range. Thus, an elevated TSH is an insensitive biomarker of iodine nutrition in adults. It may, however, be a sensitive indicator of iodine status in the newborn period.[17] Serum TSH concentrations are increased in iodine-deficient infants for the first few weeks of life. As demonstrated in national data from Switzerland,[23] if less than 3% of newborn TSH values are above 5 mU/L in whole blood collected 3 to 4 days after birth, this suggests iodine sufficiency in the population.[17] Otherwise, thyroid hormone concentrations are generally poor indicators of iodine status in children and adults, except in severe deficiency, when hypothyroidism develops. In mild-to-moderately deficient populations, serum T_3 increases or remains unchanged, and serum T_4 may fall, but these changes are typically within the normal range.[24]

Thyroglobulin

Tg is a thyroid-specific protein. In iodine sufficiency, only small amounts of Tg are secreted into the circulation, and serum Tg is normally less than 10 μg/L.[25] In regions of endemic goiter, serum Tg increases due to larger thyroid cell mass and higher TSH stimulation. Serum Tg is well correlated with the severity of iodine deficiency as measured by UIC.[26] Intervention studies exploring the potential of Tg as a biomarker of response to iodine prophylaxis have shown that Tg decreases rapidly with iodine repletion.[26] An assay for Tg has been developed for dried blood spots taken by a finger prick,[26] simplifying collection and transport; reference ranges are available in iodine-sufficient schoolchildren[27] and pregnant women.[28] The value of Tg to measure response to introduction of iodized salt was confirmed in a national study in Denmark, where correction of mild-to-moderate iodine deficiency decreased the prevalence of elevated Tg (>40 μg/L) from 11.3% to 3.7%.[29]

KEY POINTS

- Four methods are recommended for assessment of iodine nutrition in populations: UIC, goiter rate, TSH, and Tg. These indicators are complementary, in that UIC is a sensitive indicator of recent iodine intake (days), and Tg shows an intermediate response (weeks to months), whereas changes in the goiter rate reflect long-term iodine nutrition (months to years).

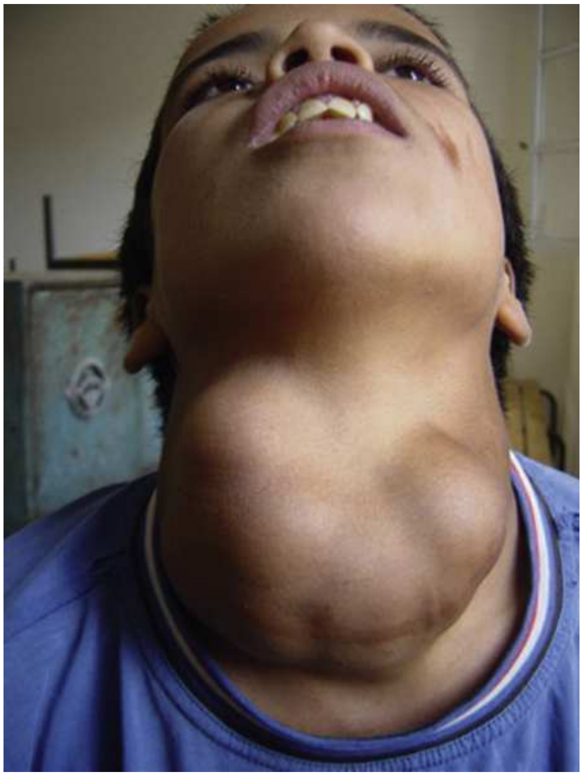

Fig. 76.1 Nodular goiter in a 14-year-old boy photographed in an area of severe iodine deficiency disorders in northern Morocco, with tracheal and esophageal compression and hoarseness, likely due to damage to the recurrent laryngeal nerves. Fig. 76.2 Neurologic cretinism in a 9-year-old girl from western China with the characteristic features: severe mental deficiency together with squint, deaf mutism, and motor spasticity of the arms and legs. (Photograph courtesy of M.B. Zimmermann, Zurich, Switzerland.)

EFFECTS OF IODINE DEFICIENCY ON THE THYROID AND BRAIN

Goiter

Goiter is the classic manifestation of iodine deficiency. Iodine-deficiency goiters are initially characterized by diffuse, homogeneous enlargement, but over time nodules often develop (Fig. 76.1). Iodine deficiency sharply increases risk for multinodular toxic goiter, primarily in women older than 50 years.[9] Many thyroid nodules derive from a somatic mutation and are of monoclonal origin[30]; the mutations appear to be more likely in nodules under the influence of a growth promoter, such as iodine deficiency. In mild iodine deficiency, there is frequently only mild enlargement of the thyroid, and the characteristic histologic findings are hyperplasia with abundant parenchyma, high follicular epithelium, and rare colloid. In chronic severe deficiency, repeated episodes of hyperplasia followed by involution and atrophy result in a thyroid with a mixture of nodules, zones of hyperplasia, and sections of involution, degeneration, and repair.

Pregnancy and Infancy

In regions of chronic iodine deficiency, women enter pregnancy with already depleted iodine stores, which, combined with low dietary iodine, reduces maternal and fetal thyroid hormone production.[31] The adverse effects of hypothyroidism *in utero* depend upon its timing and severity. T_3 is the active form of thyroid hormone in the brain, and approximately 80% of brain T_3 is generated locally from T_4.[32] T_3 plays an essential role in brain myelination and cell migration, differentiation, and maturation.[32] Fetal brain development may be sensitive to maternal hypothyroidism as early as the first trimester; nuclear thyroid hormone receptors are found in the fetal brain by 9 weeks, before full development of the fetal thyroid. Fetal thyroid function only becomes important later in pregnancy; onset of fetal thyroid hormone secretion occurs late in the second trimester, at 18 to 22 weeks of gestation.[32] Thus, maternal thyroid hormone is essential for fetal brain development during the first half of pregnancy, and severe maternal hypothyroxinemia during this period is thought to be the cause of cretinism.[33]

Cretinism is the most severe manifestation of iodine deficiency during pregnancy. The term “cretin” was originally used in Diderot’s *Encyclopedia* in 1754 to refer to “an imbecile who is deaf and dumb, with a goiter hanging down to the waist”; at that time, the condition was common in the Alpine regions of central Europe. In McCarrison’s singular description of cretinism in northern India in 1908,[34] he described a neurologic form, with predominantly neuromotor defects, and a myxedematous form, marked by severe hypothyroidism and short stature.

The three characteristic features of neurologic cretinism are severe mental retardation with squint, deaf mutism, and motor spasticity.[35] There is proximal rigidity of both upper and lower extremities and the trunk, and corresponding proximal spasticity with exaggerated deep tendon reflexes at the knees, adductors, and biceps. In addition to frank cretinism, a greater percentage of an affected population has lesser degrees of mental impairment, elevated hearing thresholds, and coordination defects[35] (Fig. 76.2).

The typical myxedematous cretin has less severe mental impairment than the neurologic cretin. Myxedematous cretins have the features of severe hypothyroidism present since early life, as in untreated sporadic congenital hypothyroidism. These include severe growth retardation,

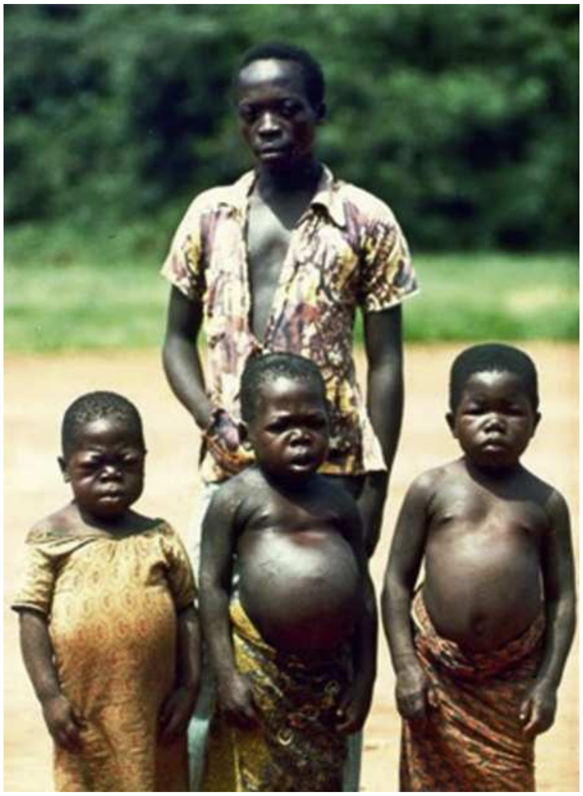

Fig. 76.3 Myxedematous cretinism in the Democratic Republic of Congo. Four inhabitants aged 15 to 20 years: a normal male and three female cretins with severe hypothyroidism with dwarfism, retarded sexual development, puffy features, dry skin and hair, and severe mental retardation. (Photograph courtesy of Professor F. Delange, Brussels, Belgium.)

incomplete maturation of the face, myxedematous, thickened and dry skin, dry and rare hair, and delayed sexual maturation.[9] Circulating T_4 and T_3 are extremely low, often undetectable, and TSH is strongly elevated. Thyroid scans typically demonstrate a thyroid in the normal location but of small size with heterogeneous and patchy distribution of the tracer. It may be difficult to clearly differentiate between neurologic and myxedematous forms of cretinism; cretinism may present as a mixed form with features of both (Fig. 76.3).

In a landmark trial in an area of severe iodine deficiency in Papua New Guinea,[36,37] alternate families received saline (control) or iodized oil injection. The primary outcome was the prevalence of cretinism at 4- and 10-year follow-up. Iodine significantly reduced the prevalence of endemic cretinism: At 4 years of age, the relative risk (95% confidence interval [CI]) was 0.27 (0.12–0.60) and at 10 years of age, the relative risk (95% CI) was 0.17 (0.05–0.58). In a study in western China, an area of severe iodine deficiency and endemic cretinism, participants were groups of children from birth to 3 years and women at each trimester of pregnancy.[33] Untreated children 1 to 3 years of age, studied when first seen, served as controls. The intervention was oral iodized oil, and treated children and the babies born to the treated women were followed for 2 years. The prevalence of moderate or severe neurologic abnormalities among the infants whose mothers received iodine in the first or second trimester was 2%, as compared with 9% among the infants who received iodine during the third trimester (through the treatment of their mothers) or after birth.[33] Treatment at the end of the first trimester improved neurologic outcomes. Treatment in the third trimester of pregnancy or after delivery did not improve neurologic outcomes, but developmental quotients improved slightly. The prevalence of microcephaly was 27% in the untreated children compared with 11% in the treated children. The mean (± standard deviation [SD]) developmental quotient at 2 years of age was higher in the treated than in the untreated children (90 ± 14 vs. 75 ± 18).[38]

The cognitive deficits associated with iodine deficiency may not be limited to severely iodine-deficient areas. Two observational studies in high-income countries reported lower IQ and poorer school performance in children born to mildly iodine-deficient mothers[39,40]; others comparing different doses of iodine supplements did not.[41] In randomized controlled trials of iodine supplementation in mild-to-moderately iodine-deficient pregnant women in Europe, iodine treatment reduced maternal and newborn thyroid size, and, in some, decreased maternal TSH.[31] However, none of the trials found an effect on maternal and newborn total or free thyroid hormone concentrations, which are likely the best surrogate predictors of infant development.[42] A recent multicenter trial randomized pregnant women in India and Thailand ($n = 832$; mUIC 131 μg/L) to receive daily 200 μg oral iodine or placebo until term.[43] Supplementation had no effect on child neurodevelopment measured at 1, 2, and 5.4 years. These studies are reassuring in that they suggest that, in areas of mild-to-moderate iodine deficiency, the maternal thyroid is able to adapt to meet the increased thyroid hormone requirements of pregnancy.[31] The American[44] and European Thyroid Associations[45] recommend women take an iodine supplement during pregnancy in areas of even mild deficiency. In contrast, WHO does not recommend maternal iodine supplements in countries with well-functioning iodized salt programs,[46] concluding that, if women are iodine-replete before conception, they can cover their requirements during pregnancy by increasing fractional clearance of plasma iodide and drawing from thyroidal iodine stores.

In areas of severe iodine deficiency, lower maternal T_4 concentrations predict higher infant mortality, and the infant mortality rate may decrease if iodine deficiency is corrected before or during pregnancy.[47] Delong et al.[47] added potassium iodate to irrigation water in three areas of severe iodine deficiency in China and found a large reduction in both neonatal and infant mortality in the following 2 to 3 years compared with areas that did not receive iodine. In Algeria, compared with untreated women, rates of spontaneous abortion, stillbirth, and prematurity were significantly lower in women treated with oral iodized oil during pregnancy.[48] A randomized, placebo-controlled trial of oral iodized oil (100 mg iodine) was conducted in Indonesia to evaluate the effect on infant mortality.[49] The iodine or placebo was given with oral poliovirus vaccine; infants ($n = 617$) were treated at approximately 6 weeks of age and were followed for 6 months. There was a 72% decrease in risk of infant death during the first 2 months of follow-up.[49]

Childhood

Two recent systematic reviews[50,51] have confirmed the benefits of correcting iodine deficiency. The first looked at 89 studies that provided iodized salt to pediatric and adult populations and found a significant 72% to 76% reduction in risk for low intelligence (defined as IQ <70) and an 8.2- to 10.5-point overall increase in IQ.[50] The second review similarly reported that iodine-sufficient children have a 6.9- to 10.2-point higher IQ than iodine-deficient children.[51] Although the overall quality of the studies included in these analyses was low, they imply that individuals, and particularly children, with chronic, severe iodine deficiency experience a mean reduction in IQ of 7 to 11 points. Two high-quality randomized trials in school-aged children have assessed the effect of iodine treatment on cognition.[52,53] A 6-month intervention trial in moderately iodine-deficient 10- to 12-year-old children in Albania given either 400 mg of iodine as oral iodized oil or placebo[52] reported that iodine increased mean circulating T_4 by approximately 40% and improved several cognitive and motor tests. A controlled trial in mildly iodine-deficient 10- to 13-year-old children in New Zealand[53] gave a daily tablet containing 150 μg iodine as potassium iodide (KI) or placebo for 28 weeks. The overall cognitive score of the iodine group was 0.19 SDs higher than that of the placebo group. Therefore, available data suggest that in children raised in areas of mild-to-moderate iodine deficiency, cognitive impairment is at least partially reversible by iodine repletion.

Adulthood

Iodine status is an important determinant of thyroid diseases in adult populations.[20] Iodine deficiency predictably increases risk for diffuse goiter and thyroid nodules.[20] Severe iodine deficiency causes hypothyroidism because, despite an increase in thyroid activity to maximize iodine uptake and recycling, iodine intakes are simply too low to maintain thyroid hormone production. In mild-to-moderate iodine deficiency, the thyroid gland is able to compensate for low dietary intake by increasing thyroid activity, which maintains thyroid hormone production, but at a price: in many individuals, chronic stimulation of the thyroid leads to thyroid nodularity and autonomy.[20] This increase in nodularity subsequently increases risk of hyperthyroidism if iodine intakes are increased by iodized salt.[20] However, this increased risk of hyperthyroidism in the population is transient, as iodine sufficiency normalizes thyroid activity; in the long term, this reduces nodularity and autonomy.[20,54] The small increase in mild subclinical hypothyroidism in mainly younger adults during a shift from low to high iodine intakes may be due to increased thyroid autoimmunity and might also be transient, but more long-term studies are needed. In a survey across China 20 years after the implementation of salt iodization, iodine deficiency was significantly associated with most thyroid disorders, while excessive iodine intake was only associated with an increased prevalence of subclinical hypothyroidism and clinical hyperthyroidism.[55]

Available evidence from animal and epidemiological studies suggests iodine deficiency is a risk factor for follicular thyroid cancer, and possibly for anaplastic thyroid cancer.[56] However, the overall incidence of thyroid cancer in populations does not seem to be affected by the usual range of normal to high iodine intakes from dietary sources.[57] A pooled analysis of 13 case-control studies reported a significant decrease in thyroid cancer risk with high fish consumption (a surrogate for iodine intake) in regions with endemic goiter (odds ratio 0.65, 95% CI: 0.48–0.88) but not in iodine-rich regions (odds ratio 1.1, 95% CI: 0.85–1.5).[58] Although several ecological studies have suggested an increase in papillary thyroid cancer after the introduction of iodized salt to populations, confounding environmental factors and increasing diagnostic intensity limit their conclusions.[56,59] Finally, a recent metaanalysis of eight case-control studies, including data from China (n = 4974), found that more than adequate or excess iodine intake (>300 mg/d) was associated with a 23% decrease in risk for thyroid cancer.[60] Over the past three to four decades in the United States, the prevalence of thyroid cancer has been steadily increasing, but iodine intakes during the same period have decreased by over 50%.[56] Thus, a higher intake of dietary iodine may be a protective factor against thyroid cancer,[56] but more high-quality case-control studies are needed in this area.

KEY POINTS

- Iodine deficiency has multiple adverse effects on growth and development; these result from inadequate thyroid hormone production due to lack of sufficient iodine. During pregnancy, iodine requirements increase sharply, and iodine deficiency during pregnancy can impair cognitive development of the offspring.

Epidemiology of Iodine Deficiency

The WHO's first estimate of the global prevalence of goiter in 1960 suggested that 20% to 60% of the world's population was affected by iodine deficiency.[61] The International Child Development Steering Group subsequently highlighted iodine deficiency as one of four key global risk factors for impaired child development.[62] Programs against iodine deficiency are appealing for national governments, because the health and economic consequences can be prevented by salt iodization, a low-cost and sustainable intervention. Between 1942 and 2020, 123 countries introduced mandatory legislation on salt iodization. In 2021, 124 countries have legislation for mandatory salt iodization, and 21 have legislation allowing voluntary salt iodization.[63] Salt is considered adequately iodized when the fortification level is 15 to 40 ppm.[64] The United Nations Children's Fund estimated that, in 2018, 88% of the global population used iodized salt.[65]

The Iodine Global Network (IGN) assembles data from iodine surveys conducted throughout the world and continually monitors global iodine status.[66] In population iodine monitoring, the WHO recommends that iodine status in school-age children serve as a proxy for the general population[17]; therefore, in the IGN Scorecard, emphasis is given to studies in school-age children. Cross-sectional studies measuring UICs have been conducted in 152 out of 194 countries in the past 15 years: in 133 countries, the studies were nationally representative.[66] The number of countries with adequate iodine intake doubled over the past 20 years and increased from 67 in 2003 to 105 in 2011 and to 117 in 2021,[66] proving the effectiveness of salt iodization. However, in 2021, 21 countries still have insufficient iodine in their diets (Fig. 76.4). Iodine intake is lowest in Madagascar, where the mandatory salt iodization program recently fell apart due to political instability. In Vietnam, weakening of the previous mandatory standard allowed the introduction of noniodized salt, and iodine status deteriorated. Several large countries have incomplete nationwide coverage and strong regional variations in iodine status, e.g., Sudan and Russia. Iodine intake is low in several countries with strong health systems and otherwise successful public health programs (Norway, Germany, and Finland); in these countries, a major challenge is the low use of iodized salt in the production of processed foods. On the other hand, 14 countries have excessive iodine intake, as defined by a mUIC greater than 300 μg/L.[66] Excess iodine intakes in populations can result from iodine-rich groundwater (e.g., Somalia) and/or diets that are naturally high in iodine (e.g., South Korea). Iodine excess can also occur when the level of iodine added to salt is too high considering per capita salt intakes (e.g., Colombia). The WHO recommends setting the salt iodization level based on estimated per-capita salt intakes: in populations where mean salt intake per capita is 5 and 10 g/day, salt should be iodized at 40 and 20 ppm, respectively.[67] In situations where monitoring suggests excess intakes, the salt iodization level should be reduced to bring the population mUIC to less than 300 μg/L. A good example is Brazil, where, in response to surveys showing excess iodine intakes, the fortification level of iodine in salt has been reduced to 15 to 45 mg.[68] Thus, regular monitoring of salt iodization programs and population iodine status can help prevent both iodine deficiency and iodine excess.

KEY POINTS

- The number of countries with adequate iodine intake has increased from 67 in 2003 to 117 in 2021, but 21 countries still have insufficient iodine intake, while 14 countries have excessive iodine intake, either due to groundwater iodine or overiodized salt.
